I. INTRODUCTION

Any interactive graphics program is more complex than the usual "sample program" unless its only function is to plot a simple picture. If the program also defines and manipulates a data structure containing relational information about the problem, the complexity of the program rapidly increases. This example attempts to provide the "flavor" of a program which performs a useful function, but with enough simplifying assumptions to make it tractable as a demonstration program.

A variety of applications suitable for treatment using interactive graphics can be considered as a variation upon the basic problem of building, editing and analyzing networks. Examples of this type of problem are computer program flowcharting, design of piping networks, construction of PERT diagrams and the design of electrical circuits. A typical program of this type having sufficient facilities to make it useful to a professional in the applications field would run well over 100 pages of listings in a high-level programming language. In order to provide a vehicle for treating many of the issues important in the design and implementation of interactive graphics programs, a simple network drawing and editing program was implemented. The program could have been designed to deal with 'black boxes' and their interconnections. However, in order to give the program some degree of reality, the network components are represented by components from electrical engineering, but the program was designed as a

teaching vehicle rather than as a useful program for circuit design. It is therefore completely unnecessary to know anything about electrical engineering; components may be treated as different flavors of black boxes.

The program would have to be expanded considerably to be useful for circuit design and analysis, both in the types of elements it can handle and in the analysis routines provided, which are completely missing in this case. Therefore, the sample program should be regarded as being only a fraction of the size and complexity of a useful on-line circuit design system; the principal limitations are summarized in Section IX. In studying the program, one should regard the example as a vehicle to illustrate:

1. typical manipulations upon complex data structures,
2. programming techniques used to allow a user to interact with a program through the use of "light buttons",
3. the correlation of graphic input with the program data structure,
4. high-level language facilities which facilitate graphics programming.

The program allows the user to construct an electrical circuit containing nodes, capacitors, resistors, and short circuits, to modify the circuit, and to assign names and values to resistors and capacitors.

In order to specify large circuits, it is desirable to be able to define _devices_. A device is a circuit which will be used as a unit in building a larger circuit; it will be represented whenever it is used by a unique symbol. For example, it is simpler to use a symbol to represent a transistor than to draw the circuit defining the transistor every time a transistor is needed. It is frequently necessary to be able to substitute the definition of a device (i.e., the circuit specifying it) for its symbol when the properties of the circuit are being investigated. A device in the sample program serves much the same purpose as does a subroutine in a programming language; if the network problem considered had been computer program flowcharting, each subroutine would have a unique symbol to represent a call to it. As would be expected, a device can always be defined using previously defined devices and the basic circuit components, nodes, capacitors, resistors and shorts. The device definition must specify how it can be connected when used, just as the definition of a subroutine must include the number of arguments. The definition, usage and editing of devices is one of the more sophisticated portions of the sample program.

II. DISPLAY EQUIPMENT USED

The sample program has been designed to operate upon a display terminal using a storage CRT rather than the more usual type of terminal which continuously redisplays the picture. When a storage CRT is used, the image is transmitted to the terminal only once and is stored locally within the display tube. The display can be partially altered only for additions; to delete any portion of the picture, all the information on the screen must be erased and the display regenerated with the alterations. As the picture is drawn only once, light pens cannot be used with storage CRT displays, but a device such as a joystick driving a cursor can be used to point to objects; this mechanism is handled locally at the console. Applications that involve frequent picture changes, such as animated movies or the rotation or translation of objects, cannot be performed using a storage CRT terminal. However, for those applications for which it is sufficient, the cost of a commercially available terminal including a keyboard and graphic input facilities is about $10,000.

The terminal used for operating the sample program is the Advanced Remote Display Station (ARDS) which was developed at the M.I.T. Electronics System Laboratory as a remote display for a time-sharing system (2,3). The main design requirement was a graphic terminal that could operate over switched voice-grade telephone lines using the full ASCII character set with

minimum demands on the time-sharing system. The terminal includes a character generator and line generator. For graphics the display screen is defined to contain 1081 X 1415 addressable, but not necessarily resolvable, points; the point with x and y addresses 0,0 is in the center of the screen.

Two types of graphic input devices are available, a joystick and a "Mouse," both of which can be used to position a cursor on the screen. A feature of the terminal design is that the cursor can be displayed at an intensity sufficient to make it visible, but insufficient to cause it to store on the screen. Buttons are provided on the graphic input devices which allow either the cursor position, or the relative vector from the last beam position, to be transmitted.

The sample program was written using this terminal in order to illustrate that useful interactive programs can be created using reasonably-priced hardware which can communicate with computers over voice-grade telephone lines (preferably at speeds of at least 1200 baud). In addition, the program illustrates how the pointing function can be implemented using devices other than light pens.

III. PROGRAM FUNCTIONS

The program allows the user to perform the following seven functions:

1. To begin drawing the circuit by specifying a point on the screen where the first node is to be defined. A node is a point of intersection of circuit elements and can only occur at specified grid points on the screen.

2. To draw, from the node last indicated with the graphic input device, an element which may be:

   a. a horizontal capacitor, resistor or short circuit

   b. a vertical capacitor, resistor or short circuit.

3. To define as a device a circuit to be drawn, and to assign a symbol and a name to a device.

4. To use the device in constructing a circuit.

5. To delete a device, a node or an element pointed to by the graphic input device.

6. To assign a value to a resistor or capacitor.

7. To edit a device definition in order to alter the elements comprising the equivalent circuit for the device.

The user operates the program by using the graphic input device to point to a "light button" in order to indicate the program option desired. Nodes, devices and elements of interest are also denoted using the graphic input device. Values and names for devices, capacitors and resistors are input via a keyboard.

A light button is a descriptive phrase displayed on the screen to indicate a program option. When the user points

to a phrase with the graphic input device, the program identifies the light button and associates it with information in the program's data structure which indicates the proper action to be taken. In this program two sets of light buttons, or "menus," are used, one for operations upon the main circuit and one for operations involving devices. If changing the menu did not involve erasing the screen and rewriting all the information on it, which may take several seconds when using the ARDS terminal on a telephone line, more selective menus could have been used to further reduce the user options to include only those which the user could employ within the present context of his work. The two menus are shown on the next page.

This empty page was substituted for a blank page in the original document.

LIGHT BUTTONS

Light Button Text	Functions
DELETE	Delete a node, element or usage of a device
VALUE	Assign a value to a resistor or capacitor
HORIZ RESISTOR	Draw a horizontal resistor to the right from the node previously specified
VERT RESISTOR	Draw a vertical resistor down from the node last specified
HORIZ CAPACITOR	Draw a horizontal capacitor
VERT CAPACITOR	Draw a vertical capacitor
HORIZ SHORT	Draw a horizontal short
VERT SHORT	Draw a vertical short
AUTO ERASE ON	Set mode to erase and redraw the display whenever a deletion occurs
AUTO ERASE OFF	Opposite of AUTO ERASE ON (Normal program mode)
ERASE AND REDRAW	Erase the screen and redraw the picture immediately
QUIT	Terminate program execution, returning control to the timesharing system command level
ATTACH DEVICE	Replace a node previously specified with a device to be specified
TERMINATE	Terminate the device definition which is being defined or edited
DEFINE DEVICE	Begin a device definition, saving the present state of the main circuit for use when the definition is terminated
EDIT DEVICE	Retrieve a previously defined device for editing, saving the present state of the main circuit until the editing is terminated

The TERMINATE light button only occurs on menu 2 and the DEFINE DEVICE and EDIT DEVICE buttons only occur on menu 1. All other light buttons are on both menus.

IV. MODELING THE CIRCUIT

If the program is to deal with the circuit, it must have access to certain information about it. For instance, one might want to know what is the value of capacitor "C3". To answer this question, the program must have stored the fact that there is an element named "C3" which has a certain value. But a circuit is more than just data of this type. Editing operations, such as deleting a node, require a knowledge of many relationships ; to delete a node, one must remove all of the elements of any type attached to it. This type of information will be called structure. Each node or element in the circuit has certain data pertaining to it and there is a structure which interrelates the nodes and elements.

The following data items are stored for each node :

1. A "name".
2. An X and Y position in some system of coordinates.
3. The number of elements attached to the nodes.

The structural information for each node specifies which elements are attached to the node.

For a resistor or capacitor, the program stores as data :

1. The value of the resistance or capacitance.
2. A "name" so the user can refer to the element.

The structural information for an element specifies the two nodes to which the element is connected. For an element representing a short circuit one need store, in this example, only the nodes between which the short is connected. All of the data plus the structure indicating

relationships between the individual parts of the model is called the model's data structure.

Many computer representations of these elements and their interconnections can be devised. To create a sample program we shall use the AED (Algol Extended for Design) System which has been developed by the M. I. T. Electronic Systems Laboratory Computer Applications Group and which operates on several computers, including the IBM 360 and 7094, and the UNIVAC 1108. The circuit will be modeled by using a bead, or block of contiguous storage, to represent each node or element. Each bead contains a code to indicate what type of circuit component it represents and also all the information (both data and structure) to be stored for the component. The connection of circuit components is implemented by the use of pointers; an element bead will contain a pointer which will allow the program to locate the node bead corresponding to the node to which the element is connected. Figure 1b shows the format of the data structure beads used in the program. In a resistor bead, for example, the code to indicate that the bead represents a resistor is stored in the word labelled TYPE. FROMNODE and TONODE are pointers to the node beads representing the nodes between which the resistor is connected. NAME is a pointer to the character string specifying a unique name for the resistor. VALUE is the numeric value of the resistance. Each item in a bead can be referenced symbolically by the use of the AED components feature; an item in a bead such as FROMNODE will be referred to in subsequent sections as a component of the bead. Beads are obtained from a free storage system (a storage management

system). The facilities of the AED system used in this program are described more completely in Section VIII.

V. PROGRAM OPERATIONS ON THE DATA STRUCTURE

To perform each of the functions of the program, operations must be performed on the data structure; the modification of the graphical representation of the circuit is only an obvious manifestation of the alteration made to the structure. To begin to draw a circuit the program must:

1. Obtain a block of storage, and store in it the code to indicate that it represents a node. We will call this block a <u>node bead</u>. It will contain all the information (both data and structure) about the node.

2. Store in the node bead the coordinates of the node in some coordinate system. We will use a coordinate system in which all nodes lie on grid positions separated by a Δx or Δy of 200; the center of the grid has coordinates (0, 0). The first node is drawn at the nearest grid position to the position of the graphic input device.

To draw an element (resistor, capacitor, or short) and attach it to a node, the program must:

1. Obtain an <u>element bead</u> which will contain all the information about the element; the type of element is stored in the TYPE component of the bead.

2. Find the node bead corresponding to the node the user pointed to with the graphic input device.

3. Modify the node bead to indicate a new relation exists, i.e., the element just created is to be "attached". Increase the count of the number of leads attached to the node which is stored in the LEADS component of the node bead.

4. Determine if a node already exists at the other end of the element. If not, one must be created and then the element must be "attached" to the new node.

"Attachment" of an element can be done in many ways, depending upon how relations are to be implemented in the computer. In this problem,

attachment means that pointers are stored in the node bead to indicate the elements which are attached to the node. Each element bead contains pointers to the two node beads representing the two nodes to which it is connected.

To delete an element pointed to by the graphic input device the program must:

1. Find the element bead corresponding to the element to which the user pointed with the graphic input device.

2. Locate the nodes to which the element is attached, and set the pointers to indicate that the element is no longer connected and reduce the count of the number of leads attached to the node. If no leads are attached to the node, it can also be deleted.

3. Return the element bead to the list of available storage so that it may be used again.

In addition the graphical representation of the item must be removed from the screen.

Figure 1c illustrates the data structure for a partially completed circuit; the circuit is shown schematically in Fig. 1a. For node beads only the up, left, right and down element connections are shown; for resistor, capacitor and short circuit beads only the connections to the node beads are shown. The figure also shows the pointer chain linking all nodes. This chain, which permits the program to follow pointers from one node to another, is useful since the node chain is searched frequently. Figure 1d shows the data structure as modified by adding an element, R3, between node 3 and node 6.

A more complicated program operation is deleting a node. If a node is deleted, all elements attached to it are to be deleted. Since

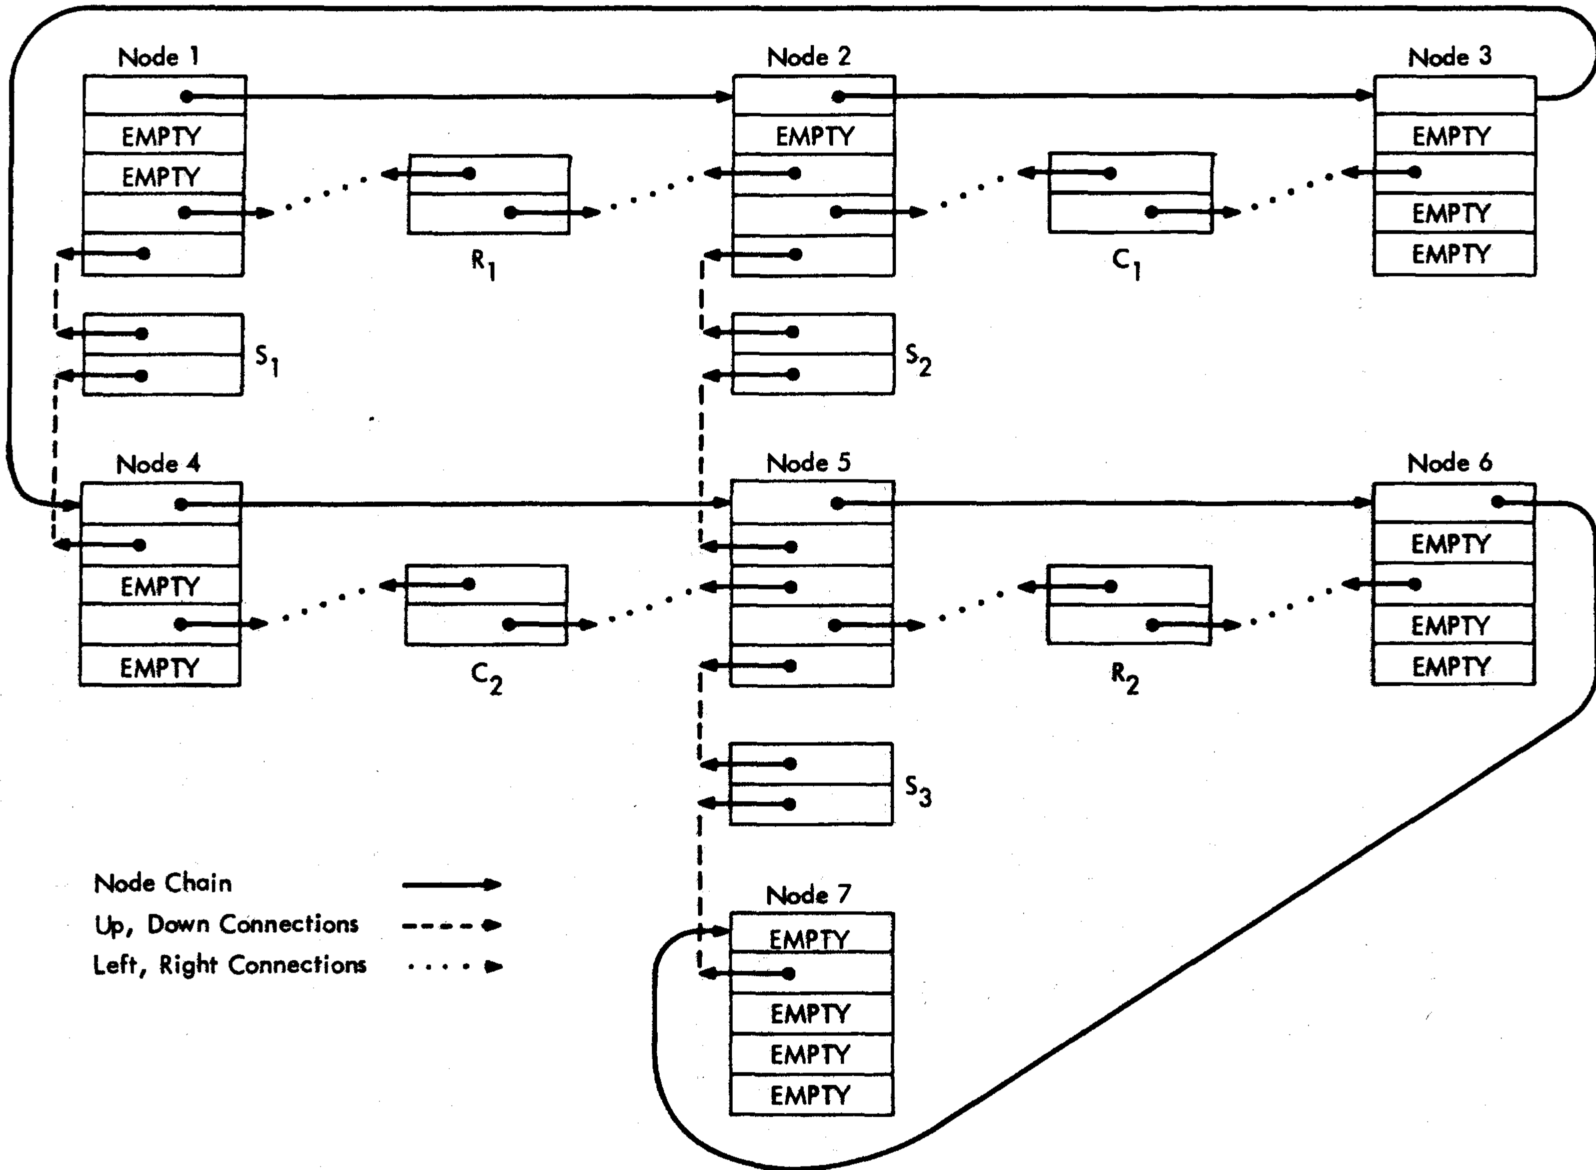

Fig. 1c Data Structure for Partially Completed Circuit

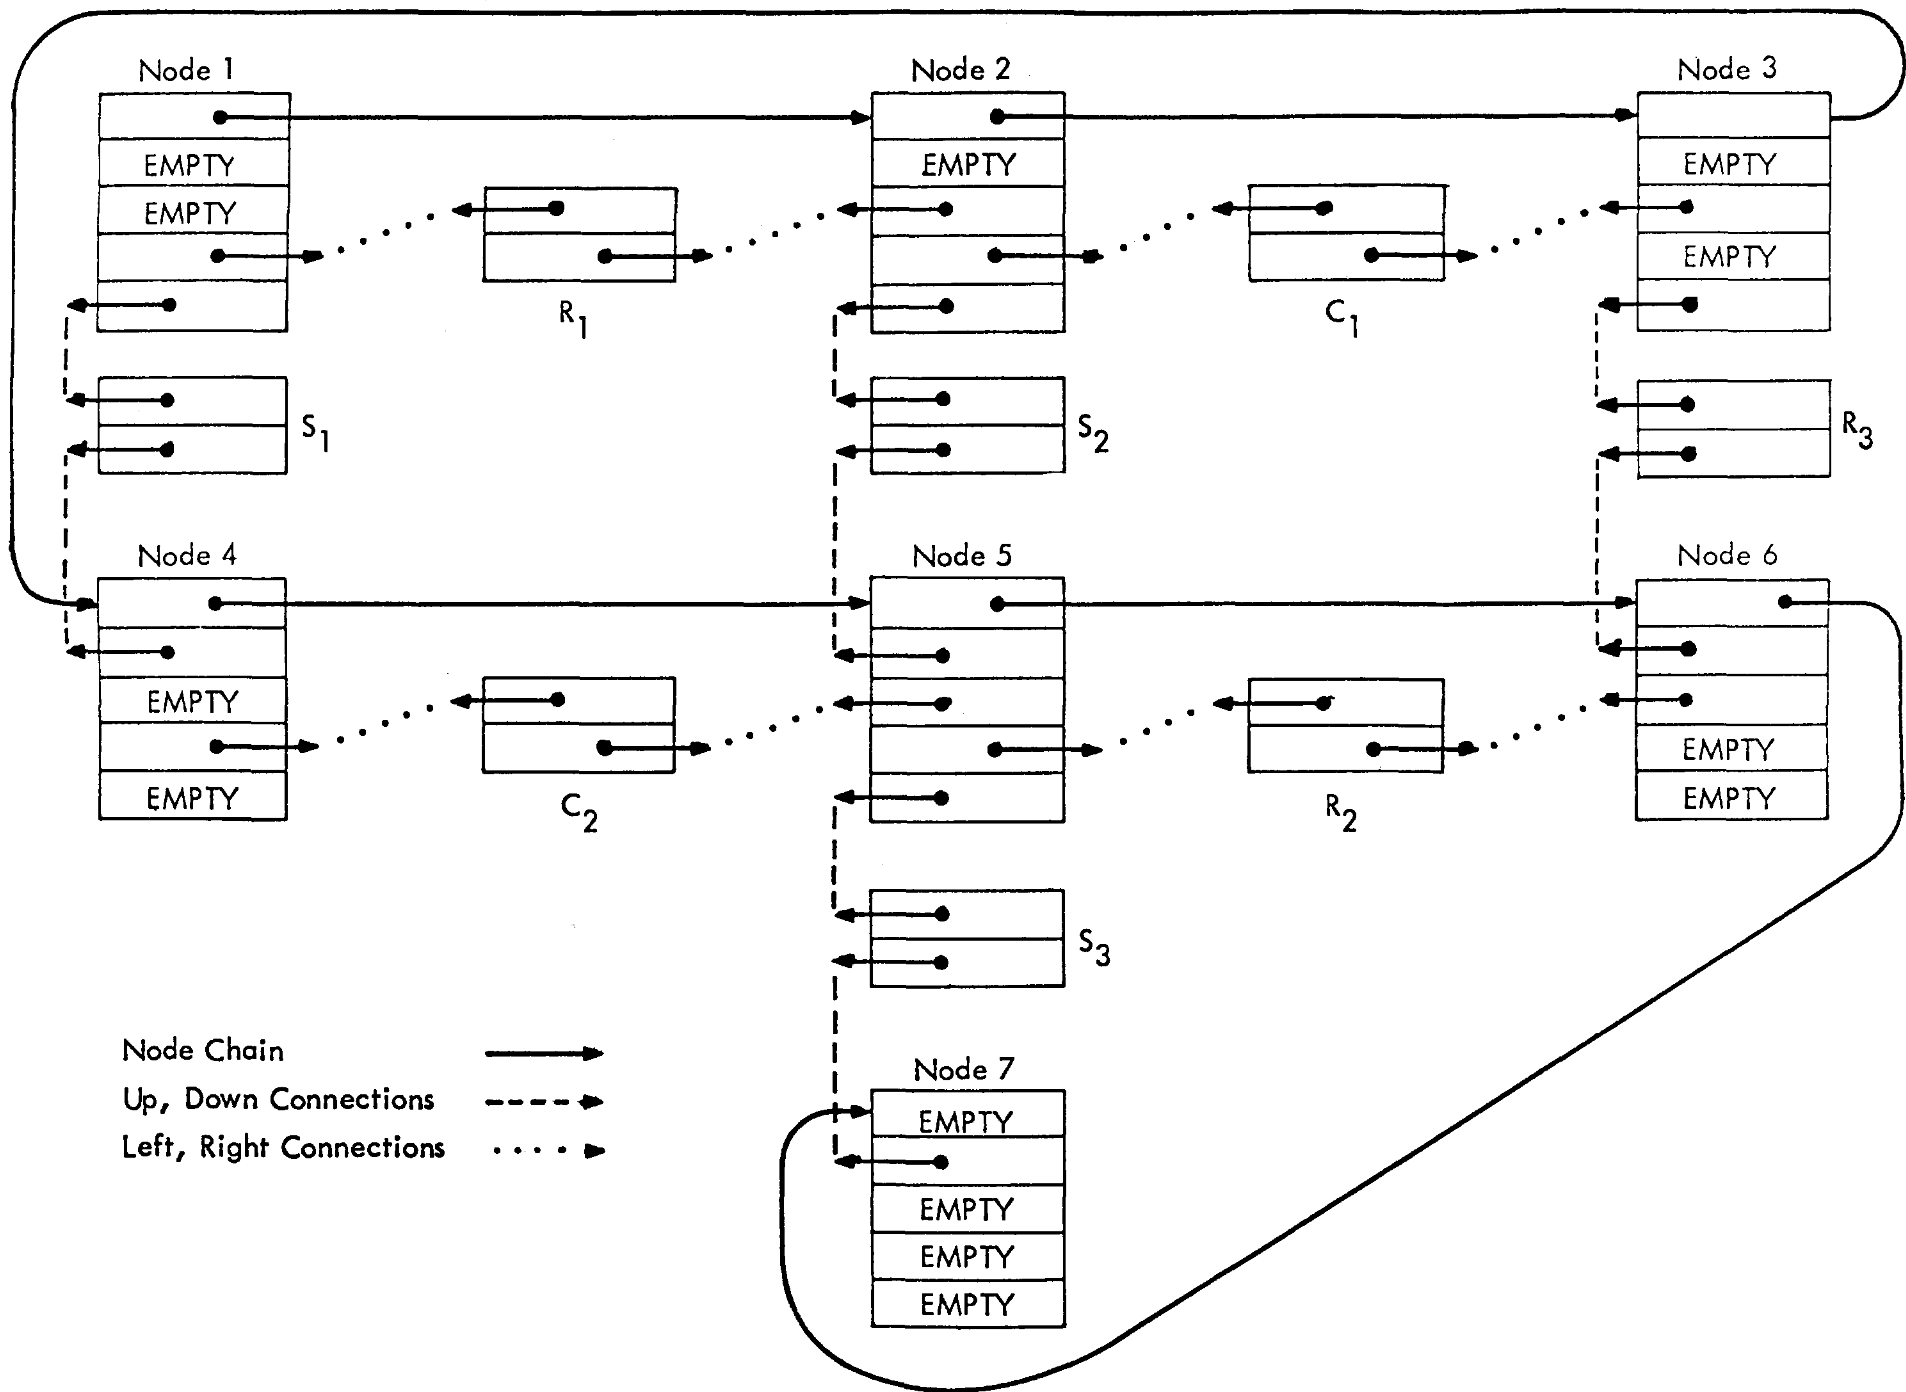

Fig. 1d Data Structure for Partially Completed Circuit with Element R_3 Added

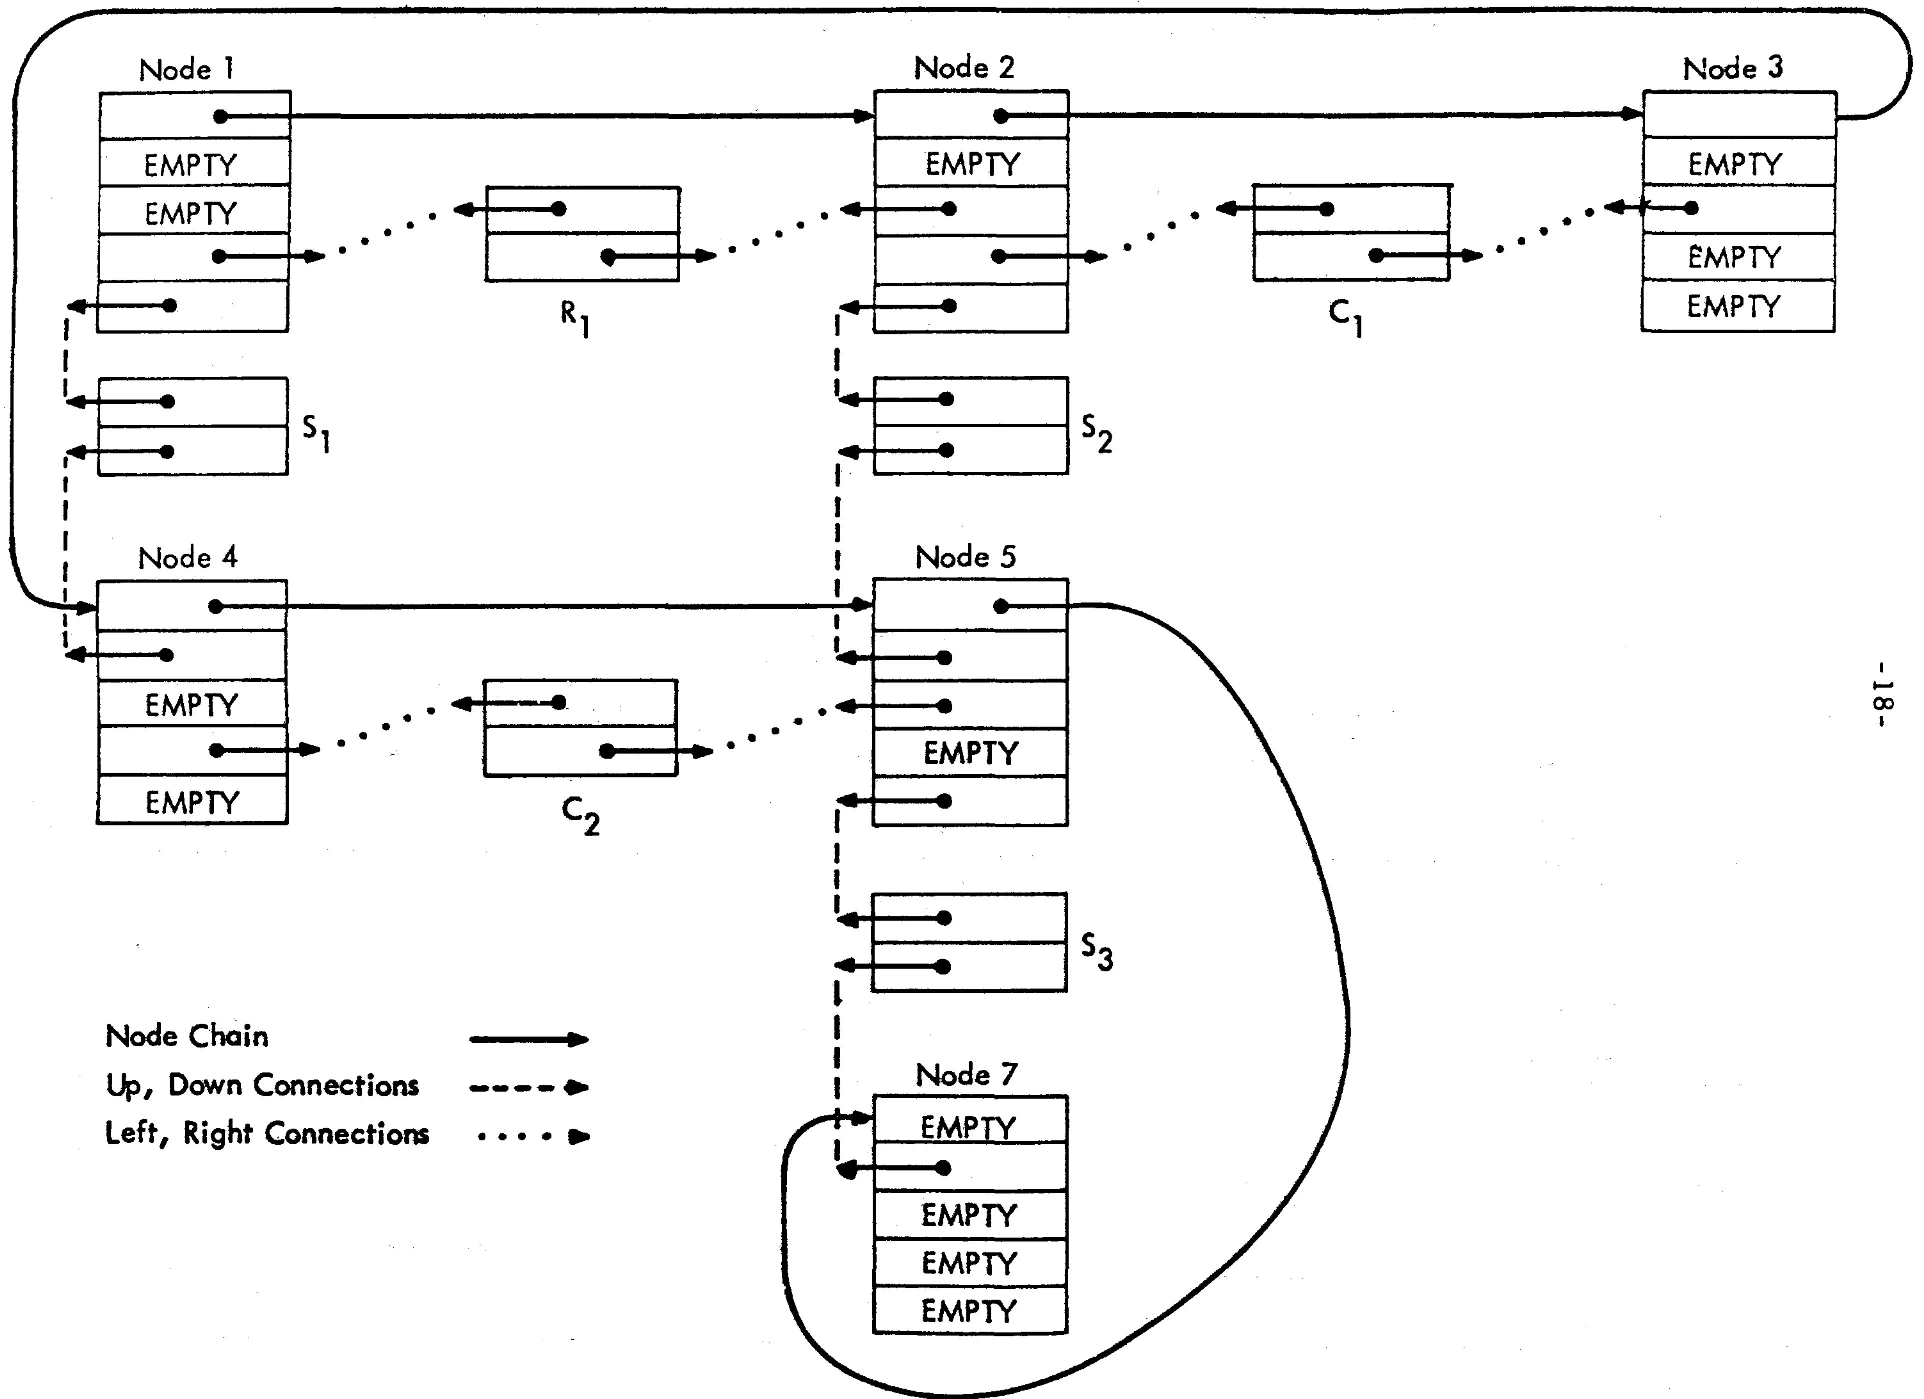

Fig. 1e Data Structure for Partially Completed Circuit with Node 6 Deleted

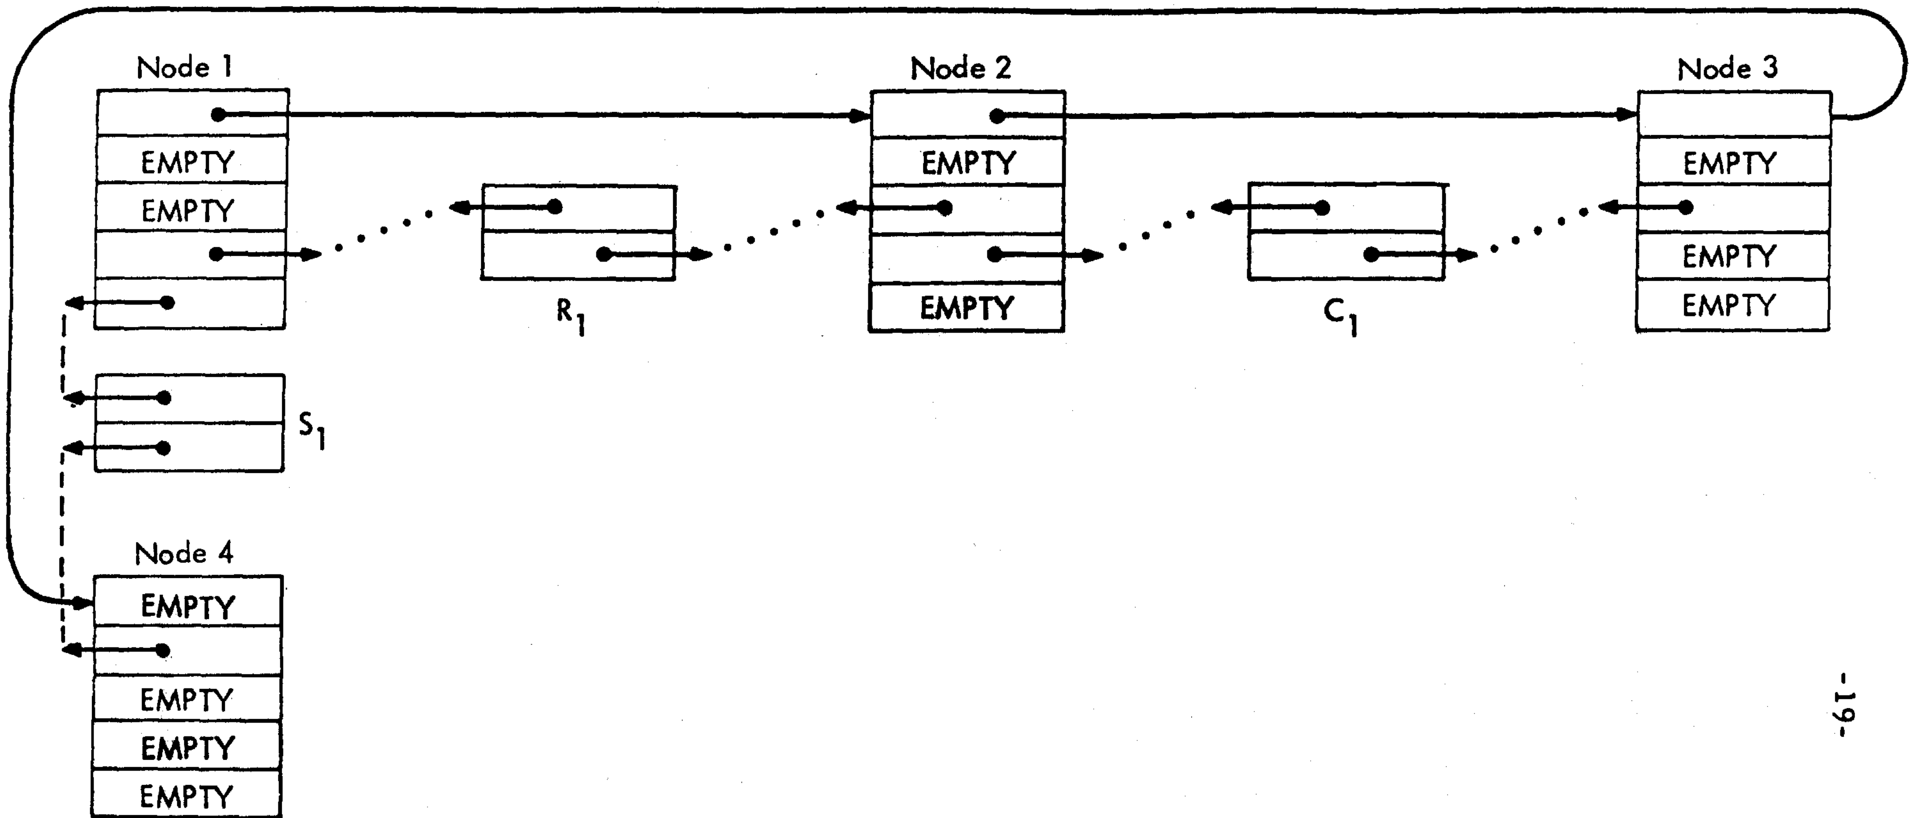

Fig. 1f Data Structure for Partially Completed Circuit with Node 5 Deleted

these elements are also attached to other nodes, one must update the information about these nodes to indicate the elements have been removed. Since the data structure implements a connection between all node beads by means of a pointer from one node bead to the next node bead, this connection must be altered to join together the nodes remaining. Of course, one must also modify the display to reflect the changes in the circuit; changing the model of the circuit in this program has no direct effect on the graphical representation of the circuit. All alterations to the display must be independently specified. Figure 1e shows the data structure in Fig. 1c after node 6 was deleted, and Fig. 1f shows the effect of deleting node 5.

The most complicated program functions are the definition, editing and usage of devices. A device must be defined before it can be used, but the definition may be begun at any time during the definition of a circuit. If a circuit, such as the one shown in Fig. 1a, is partially complete at the time a definition is to begin, the state of the circuit will be preserved until the device definition is complete and then it will be restored. The program does not allow the user to partially complete a circuit and then declare it to be a device; he must enter the device definition mode before beginning to specify the circuit which will represent the device.

The circuit representing a device, or its *equivalent circuit*, can contain elements, nodes and occurrences of previously defined devices. Each device has a user-supplied name and a symbol which indicates the number of leads the device has available for attachment. The maximum number of leads allowed is four, since in this program

a device is used in a circuit as a substitute for a node. Before a device definition is complete, a symbol having the correct number of leads must be selected. The correspondence between each lead on the symbol and the terminal nodes in the equivalent circuit for the devices must also be established. This correspondence is required so that an analysis program could properly substitute the equivalent circuit for the device in order to evaluate the properties of the overall circuit.

To define a device, the program must enter device definition mode and:

1. Obtain a device definition bead which will contain all the information about the device definition; it will contain no information about how the device is used.

2. Allow the user to design the equivalent circuit after having stored the circuit being constructed on the main circuit level. When the definition is complete, the main circuit will be restored. The FIRST·NODE component of the device definition bead points to the beginning of the data structure for the equivalent circuit.

3. Ask the user to provide a name to be given to the device and to select a symbol to represent the device when it is used. The style of symbol is given by the component BOX·STYLE in the device definition bead. The number of leads on the symbol selected is the number of terminal nodes in the circuit. A terminal node must be a node (or device) to which less than four elements have been connected.

4. Establish the connection between each lead on the symbol and a terminal node in the circuit.

5. Add the newly created device definition bead to the device definition chain, which links all device definitions.

The format of the device definition bead is shown in Fig. 2a; the data structure built when two devices are defined is shown in Fig. 2c.

DEVICE DEFINITION

FIG. 2B DEVICE USAGE BEAD

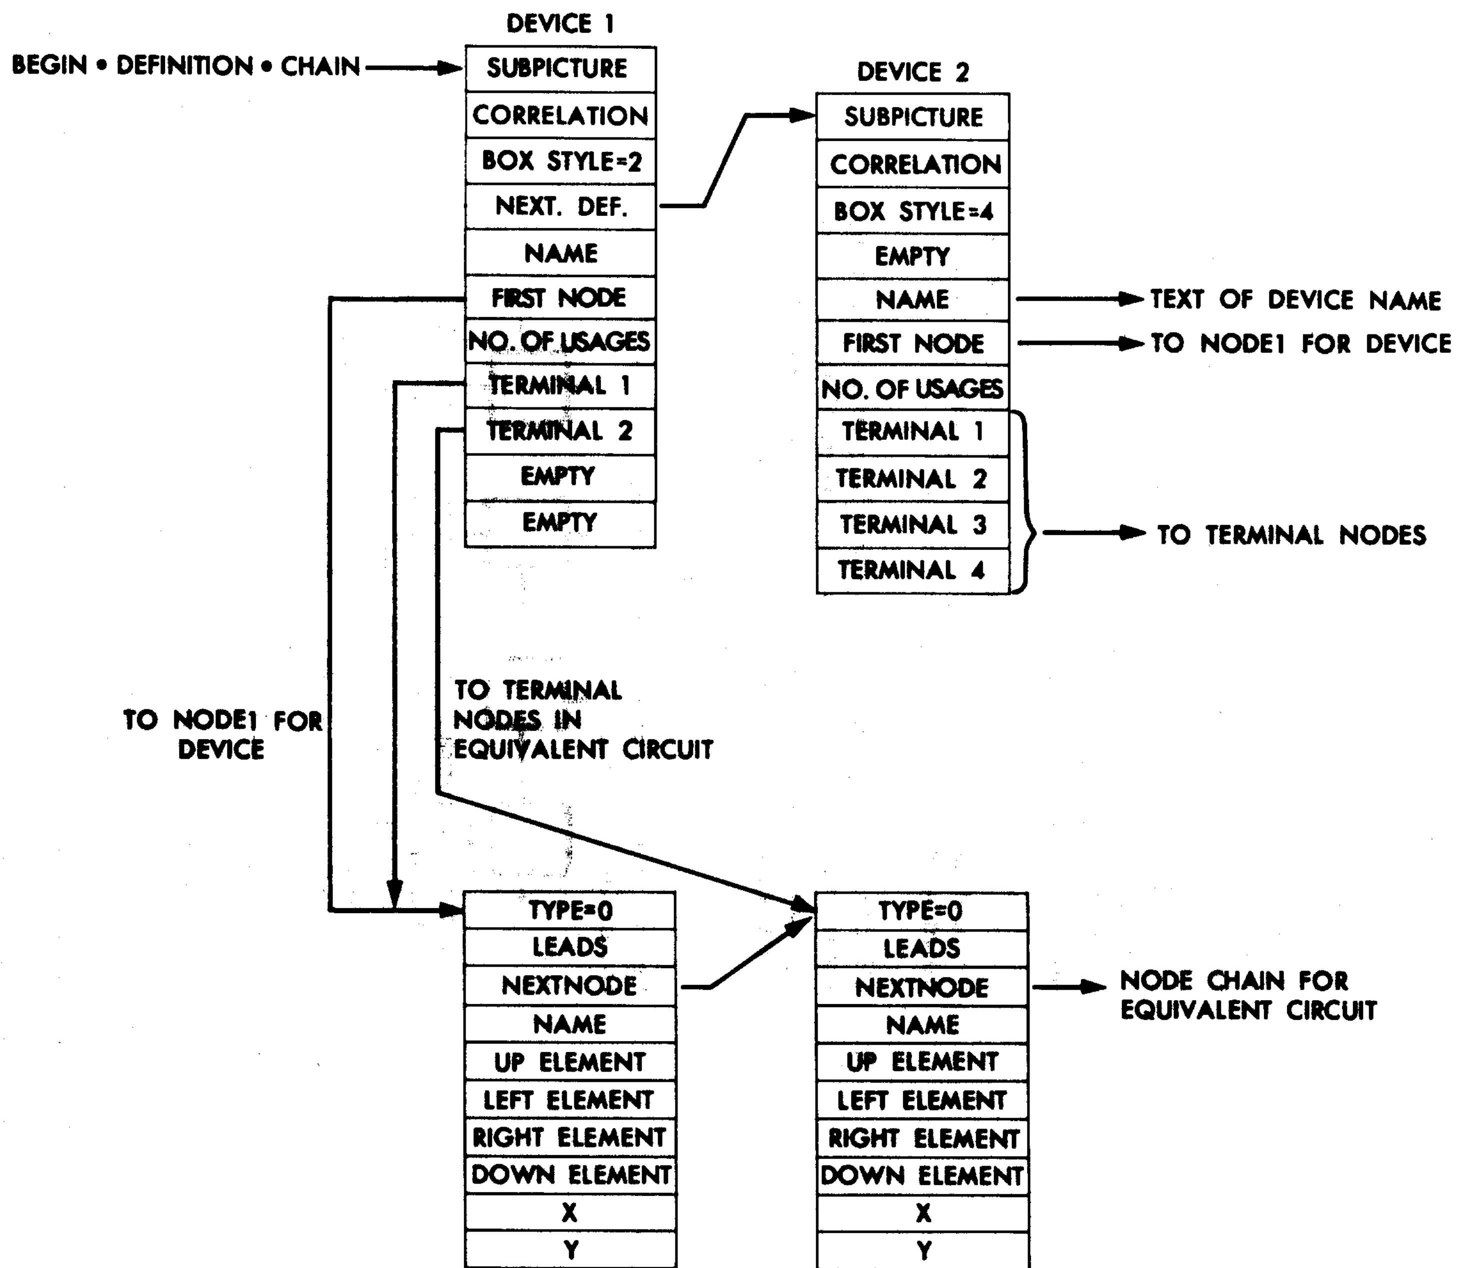

FIG. 2C DEVICE DEFINITION CHAIN FOR 2 DEVICES

To use a device in a circuit, the program must:

1. Determine that the device to be attached has been defined.

2. Obtain a <u>device usage bead</u> which will contain all the information about this usage of the device, such as the elements to which it is attached and whether or not certain leads can be used (i.e., if the device had only two terminal nodes, only two of the possible four leads can be used to attach elements). The bead also contains a pointer to the device definition bead so that the device definition could be used by an analysis program (this fact is not used in this program).

3. Delete the node at the place where the device is to be plotted. A device can only be positioned at a point where a node already exists.

4. Display the symbol corresponding to the device, including a name. The orientation of the device symbol must be specified. For example, if the user selected a symbol style such as

   
   he could insert it into the circuit in one of the four following orientations :

   
   The four orientations are displayed and the user must select the correct one with the graphic input device. The name is the one given when the device was defined concatenated with a number indicating the particular occurrence of the device.

The format of the device usage bead is shown in Fig. 2b. It should be noted the bead is nearly the same as a node, except that the type code is different, the existence of leads in certain directions may be forbidden, and the last component is a pointer to the device definition bead for the device being used.

VI. SPECIFICATION OF THE DISPLAY

The programming system that allows the different types of display consoles to be used with the M. I. T. time-sharing system (CTSS) has been given the name GRAPHSYS. (1, 4) The user interface is a set of procedure calls which allow the user to plot objects such as lines and points to remove objects from the screen, and to determine which object was "seen" by a graphic input device.

Although a display console deals only in terms of simple _console commands_ such as "draw a point" or "draw a line," the user wants to deal with objects. An _object_ is a group of console commands which are added to the display file at the same time and are to be thought of as an atomic entity, e.g., a capacitor consisting of several short, straight-line segments (made by several line-generate commands). The _display file_ is the ordered sequence of console commands which is sent to a display console to produce a picture.

A. Naming of Display Objects

When an object is placed in the display file, it must be given a unique descriptor, or name, if it is to be identified again. The user may wish to specify some object upon which GRAPHSYS should perform a function (e.g., delete this object), or GRAPHSYS may wish to inform the user of some action concerning it (e.g., this object was seen by the light pen). The _name_ is used to refer to an object in all communications between GRAPHSYS and the user; the name must be both _unique_ and _invariant_ so that an object can be uniquely identified at any time.

The form of a unique and invariant name which appears simplest, at least conceptually, is a subscript in an array. In order to perform the correlation function, which transforms (via a correlation map) the address of a console command causing a light pen interrupt to the user's name for the object, GRAPHSYS would have to build an array of length equal to the total number of names. An element in this array would contain the initial location of the console commands corresponding to the object whose name is the subscript of the element in the array. In addition, the user would need a similar array giving the item in his data structure corresponding to the name. Thus, there would be a double map, one from the user's name to the console command locations and one relating the name to the user's data structure. These maps correlate the data structure for an object with its display representation. Double maps, especially in array form, are expensive in their use of core storage.

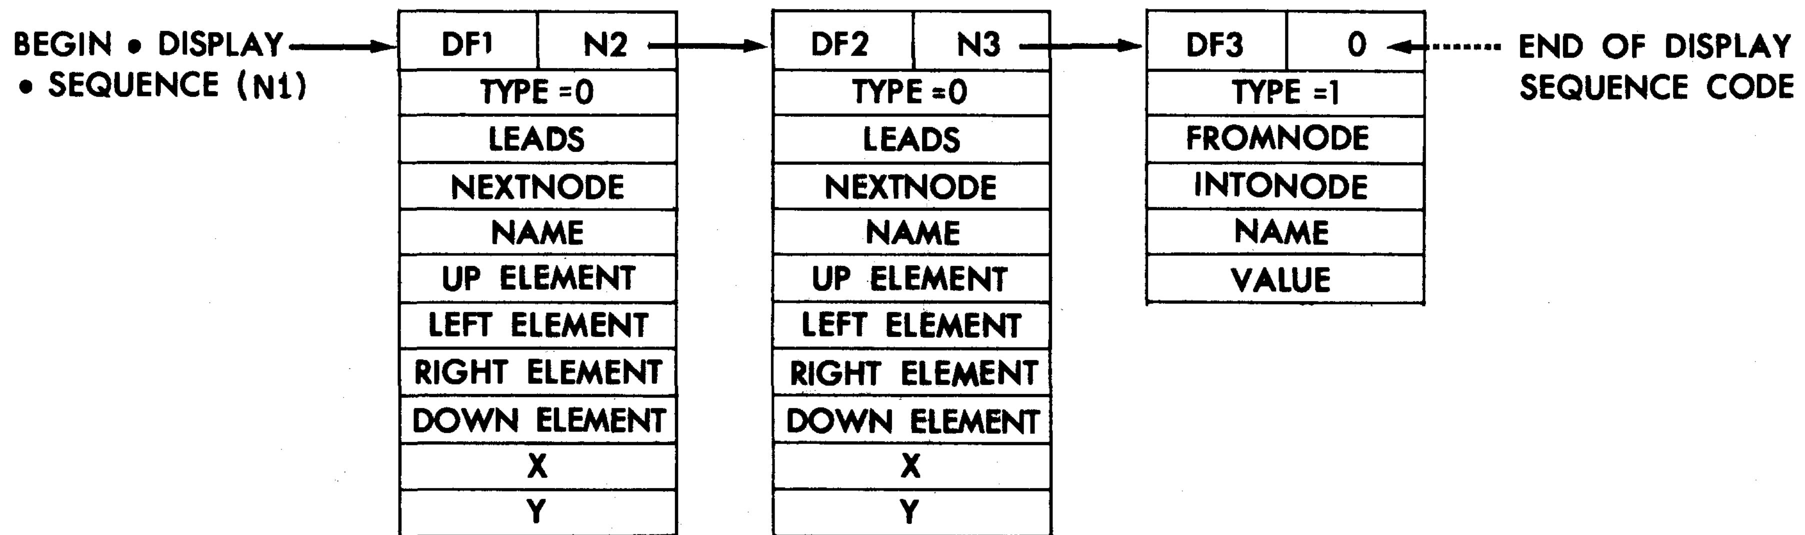
The naming scheme which has been employed by GRAPHSYS meets the criteria of uniqueness, invariance and convenience, at least within the context of an <u>in-core</u> data structure. To use the GRAPHSYS naming convention, the user extends each bead by one or two words, the <u>correlation word(s)</u> which contain the appropriate correlation information. In this manner explicit arrays are avoided,

and when the appropriate correlation word is located by the correlation mechanism, the corresponding data element (bead) is found immediately adjacent, thereby avoiding the map between the user's name and an element in the data structure. GRAPHSYS will be responsible for storing into and updating these correlation words, and performing the actual correlation. In a correlation word GRAPHSYS will store the address of the console commands for the object. The unique "name" of the object is the address of the correlation word, which is also the address of the user's data structure bead for the object.

Figure 3 illustrates the combined user-and-GRAPHSYS data structure for a display file containing three objects. In our example the correlation word(s) will occur as the first word in the entire block of storage representing an element, node or device. Each correlation word contains the name of the next object in the display sequence. The GRAPHSYS display data structure is therefore a one-way list threading through the user's data structure. A name of zero signifies the end of the list. The contents of the correlation word are maintained solely by GRAPHSYS; the user does not have to be concerned with the location of the console commands. Note also that this particular thread (list) through the beads is independent of the data associations between beads, i.e., the other list structures which the user's programs may have built.

B. Use of Subpictures

The data structure built by GRAPHSYS using the correlation words becomes more complex when subpicture calls and definitions are considered. Subpictures are defined using the procedures DEFSUB and



N1, N2, N3 are pointers to correlation words of objects; they are the GRAPHSYS "names" for the objects.

DF1 DF2, DF3 are the display file locations of display commands corresponding to the objects.

Figure 3. GRAPHSYS Data Structure

ENDSUB which work like BEGIN and END in PL/I or AED. Subpicture definitions may include calls to other subpictures to any depth, except that subpicture calls can not be recursive. Although subpictures may be defined within subpictures, they may still be called from outside those subpictures, i. e., subpictures do not possess a PL/I-type block structure. They behave exactly as if they had all been defined in parallel at the highest level.

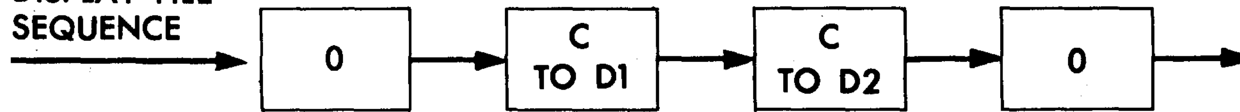
A separate list is built by GRAPHSYS linking all subpicture definitions. Each element in this list is the start of a subpicture definition and contains 3 pieces of information:

1. The number of times the subpicture is called.
2. A pointer to the first correlation word in the subpicture definition. The list beginning with this correlation word is of the same format as shown in Fig. 3.
3. A pointer to the next subpicture in the subpicture definition list.

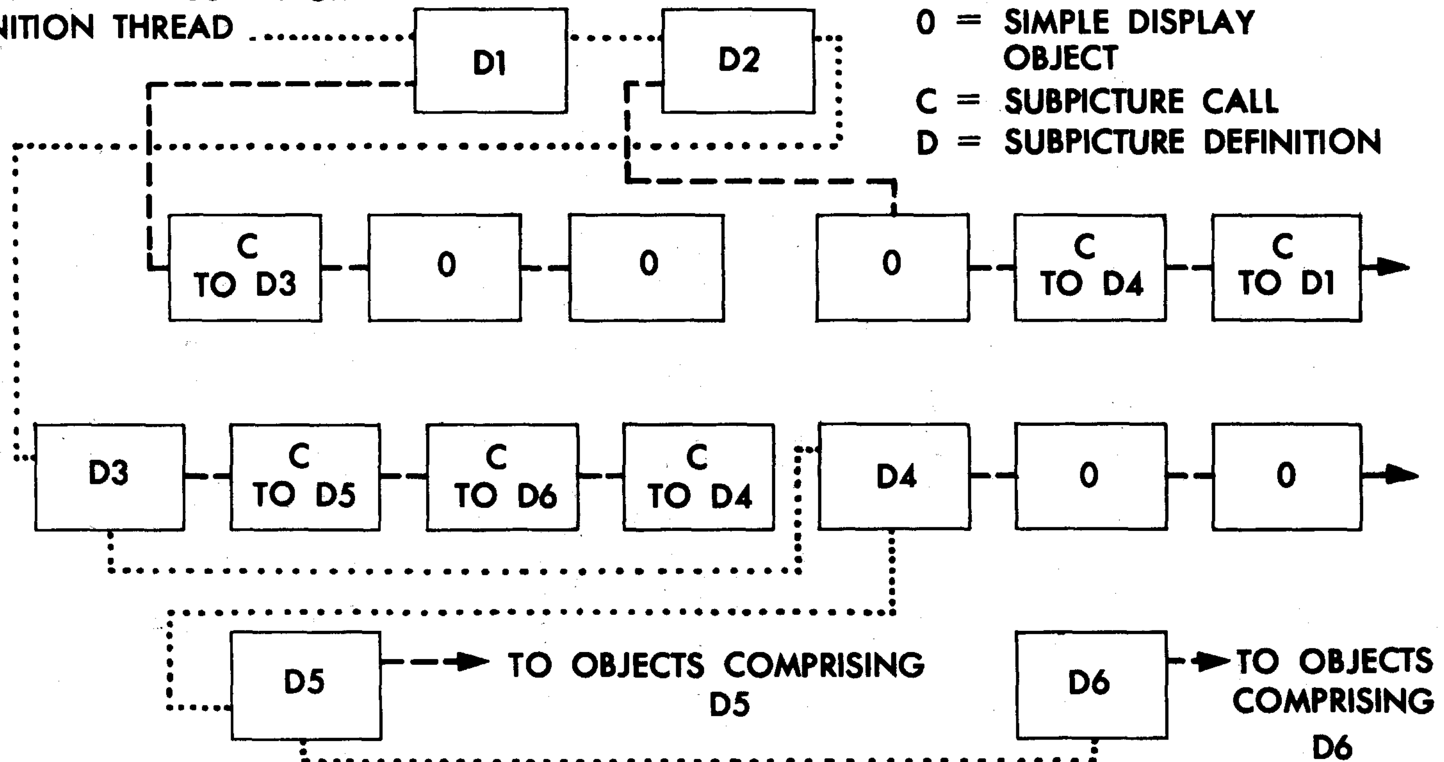
A subpicture call requires two correlation words which contain:

1. A pointer to an element in the subpicture definition list, i. e., a pointer to the beginning of the definition for the subpicture being called.
2. A pointer to the next correlation word, i. e., the next object in the display sequence following the call.
3. The display buffer address of the subpicture call (for refresh-type displays).

This structure is built automatically by GRAPHSYS and the user's only responsibility is to provide the storage used for the correlation words. Figure 4 provides a schematic view of the structure built in the following case:



BEGINNING OF SUBPICTURE
DEFINITION THREAD



MAIN DISPLAY FILE THREAD

SUBPICTURE DEFINITION THREAD

THREAD LINKING OBJECTS
COMPRISING SUBPICTURE

FIG. 4 GRAPHSYS DATA STRUCTURE WITH SUBPICTURES

1. The main display file contains an object and 2 subpicture calls, to subpictures D1 and D2.

2. The subpicture definitions corresponding to these calls are D1 and D2.

3. D1 contains a call to definition D3, and D2 contains a call to definition D4 and to definition D1.

4. D3 contains only subpicture calls, to definitions D5, D6 and D4.

The data structure built when a subpicture is defined retains the information about how the subpicture is built in terms of individual display objects. However, the same pictorial representation can be obtained by defining what is called a compound object in GRAPHSYS. A compound object is produced by combining physically the display commands from all the objects specified in order to create the display code for the new compound object. The difference between compound objects and subpictures is analogous to the difference between compiling and interpreting computer programs. In a compiled program the input statements cannot be deduced by examining the compiled code; in an interpreted program, the structure of the statements is retrievable. The data structure created at the time a subpicture is defined permits a 'pensee' to be decoded as referring to a certain object within the subpicture; in terms of the analogy it is easy for a language interpreter to report the source language statement corresponding to an execution-time error. However, if 'pensee' occurs upon a compound object, there is no information available about which object of those originally used to create the object was responsible for the pensee. Compound objects should be used when the object is the smallest piece of the picture to which the user expects to make

reference; subpictures preserve the structure used in the definition and therefore should be used if this structure is important.

When the user in the sample program defines a device, it is represented internally as a subpicture since the user may wish to modify the definition of the device in terms of nodes, devices, and elements comprising it. In order to display the equivalent circuit for the device, the subpicture for it is called. Devices may be defined in terms of previously-defined devices; this hierarchy is represented by a subpicture definition for the new device, which will contain a subpicture call to the definition for the previously-defined device. When an object within a subpicture is "seen" by the graphic input device, the identity of the subpicture call and the corresponding subpicture definition is available, in addition to the identity of the object upon which the pensee occurred. If subpicture definitions are nested, the entire subpicture hierarchy is returned upon a pensee; it is up to the user to decide how much of this history of formation is meaningful at that time.

C. Correlation of Graphic Input with Problem Data Structure

When a display with a light pen is being employed, the display hardware provides, at the time a light pen interrupt occurs, the X and Y beam coordinates and the address in the display buffer from which the current display instruction was fetched. In order to report to the user the object "seen" by the light pen, GRAPHSYS searches the data structure shown in Fig. 3, serially via the correlation word pointers for each bead (object), checking if the address resulting from the light pen interrupt corresponds to any of the display buffer locations containing the display commands to draw this object. If, for example, in

Fig. 3 the address at the time of the light pen interrupt was DF2+3 and if the object starting at DF2 had 7 display commands, the address of the correlation word of the object seen would be found by the search to be N2. Since the correlation word in this program is always the first component of the data structure bead describing the object, the user has immediate access to the data about the object.

Unfortunately, in a non-refreshed display system, such as is used in this example, the address corresponding to the display commands for the object cannot be obtained by an interrupt since only the X-Y coordinates of the cursor are available. GRAPHSYS must decide which object the user tried to designate with the cursor. The most convenient terminology to describe the correlation of graphic input with objects is by analogy with the use of a light pen. Therefore, we will use the term "pensee" to indicate a correlation between a graphic input device and a displayed object and "pen sensitivity" to indicate an object is eligible for such a correlation.

The algorithm used assumes that the area within which an object is pen sensitive is a rectangular area associated with the object. To make a displayed item "pen-sensitive" the user calls the procedure PENSNS, giving the size and the relative position of the rectangle. A special bit is set in the correlation word to indicate it is pen sensitive. If he does not wish to specify the position of the rectangle, a program-computed center is used. When the user indicates he wants to identify an object being pointed to with the cursor, GRAPHSYS searches the data structure illustrated in Fig. 4 for the first pen-sensitive object having a rectangle within which the cursor coordinates fall. A pen-

sensitive subpicture call requires that the subpicture definition be searched; upon a pensee, the name of object seen, the name of subpicture definition which includes the object, and the name of the subpicture call are returned to the user. If the subpicture call is within a subpicture definition, the names of all outer subpicture calls and definitions are also returned.

When the pen-sensitivity package is being used, the model of the picture maintained in the computer must correspond exactly to the picture on the screen. If the two differ, the user could point to an object which his program believes has been deleted, or the pen-sensitivity program may "see" an object which has not yet been displayed on the screen. In the program an object which has been deleted will be written over with a large X to indicate that it has been removed from the problem and display file data structures, but it will remain on the screen until the picture is redrawn.

D. GRAPHSYS Procedures

A variety of GRAPHSYS procedures are used in this example; they can be divided into six classes:

1. Those procedures for creating standard display objects such as lines, point, and character strings (procedures LIN, SETPT, TEXT).

2. Those procedures for modifying display objects, such as those procedures to make a line invisible, a line dotted, or to make an object pen-sensitive (INVIS, DOTTED, PENSNS).

3. Those procedures required in order to use compound objects, which are objects consisting of several standard objects; for example, an object consisting of several lines and a string of text (DEFOBJ, ADDOBJ, ENDOBJ, CRYOBJ).

4. Those procedures required in order to use sub-pictures (DEFSUB, ENDSUB, CALL).

5. Those procedures which add objects to the display file data structure and those which transmit the display file, or a portion of it, to the terminal (PLOT, DISPLAY).

6. Those procedures which alter the display file data structure by removing objects or replacing objects with other objects (RMV, RPL).

All GRAPHSYS procedures used in this program which return a value (or in FORTRAN terms are functions rather than subroutines) have a pointer as their value. A GRAPHSYS standard object is a group of display console commands which are added to the display file at the same time, and which are thought of as an atomic entity, i.e., a string of characters. The internal representation of an object is a block of storage containing the display commands with a header denoting the number of machine words in the block; the object is referenced via a pointer, which will be denoted in the procedure descriptions as PTR. A compound object consists of several standard objects which have been merged to form a single object, which is also referenced via a pointer.

Calling Sequences of GRAPHSYS Procedures

1. Procedures to create standard objects

   a. Pointer Procedure LIN
   Purpose: To build a standard object for a line.
   Calling Sequence: PTR=LIN (DELX, DELY)
   Where: PTR is a pointer to the object created,
   DELX is the Δx component of the line,
   DELY is the Δy component of the line.

   b. Pointer Procedure SETPT
   Purpose: To build a standard object for a point.
   Calling Sequence: PTR=SETPT (X, Y)
   Where: X is the horizontal coordinate of the point.
   Y is the vertical coordinate of the point.

   c. Pointer Procedure TEXT
   Purpose: To build a standard object for a text string.
   Calling Sequence: PTR=TEXT (.C. string)
   Where: .C. string is a text string generated by the AED
   .C. operator, i.e., .C. /DELETE/ (see Sect. VIII).

2. Procedures to modify standard objects

   a. Pointer Procedure INVIS
   Purpose: To make all lines or points in an object invisible.
   Calling Sequence: PTR=INVIS (PTR)
   Where: PTR is a pointer to an object, such as is produced
   by LIN or SETPT.

   b. Pointer Procedure DOTTED
   Purpose: To make all lines in an object dotted.
   Calling Sequence: PTR=DOTTED (PTR)

   c. Pointer Procedure PENSNS
   Purpose: To make an object pen-sensitive.
   Calling Sequence: PTR=PENSNS (PTR)

3. Procedures for constructing and using compound objects

   a. Procedure DEFOBJ
   Purpose: Begin a compound object definition.
   Calling Sequence: DEFOBJ ( )
   Arguments: None
   DEFOBJ must be called before ADDOBJ can be called to add
   standard objects to a compound object.

b. Procedure ADDOBJ
Purpose: To add a standard object to the compound object currently being constructed.
Calling Sequence: ADDOBJ (PTR)

c. Procedure CPYOBJ
Purpose: To make a copy of a standard or compound object.
Calling Sequence: NEWPTR=CPYOBJ (PTR)
Where: NEWPTR is a pointer to the copy.

d. Pointer Procedure ENDOBJ
Purpose: To terminate the definition of the compound object and to get a pointer to the definition.
Calling Sequence: PTR=ENDOBJ ( )
Arguments: None

4. Procedures for constructing and using subpictures

a. Pointer Procedure DEFSUB
Purpose: To start defining a subpicture.
Calling Sequence: SUBNAME=DEFSUB (SUBNAME*)
Where: SUBNAME is the pointer to a block of two words which are to be used as the correlation words for the subpicture definition. If SUBNAME is not provided, DEFSUB will obtain two words from free storage and the value of the procedure will be a pointer to the words obtained. Upon a pensee within the subpicture definition SUBNAME will be among the information returned in order to designate which definition included the object seen. A * indicates an argument optional and need not be supplied.

b. Procedure ENDSUB
Purpose: To terminate the definition of a subpicture.
Calling Sequence: ENDSUB ( )
Arguments: None

c. Pointer Procedure CALL
Purpose: To call a previously designed subpicture.
Calling Sequence: NAME=CALL (SUBNAME, NAME*)
Where: SUBNAME is the argument supplied to DEFSUB when the subpicture to be called was defined.
NAME is a pointer to a block of two words which are used as the correlation words for the subpicture call. Upon a pensee within the subpicture definition, NAME will be among the information returned in order to designate which call of the subpicture definition corresponds to the pensee.

5. Procedures to add, modify and transmit the display file

   a. Pointer Procedure PLOT
      Purpose: To add objects to the display file.
      Calling Sequence: NAME=PLOT (PTR, NAME*, AFTER*)
      Where: PTR is a pointer to the standard or compound object to be added to the display file.
      NAME and AFTER are optional arguments which may be omitted. NAME is a pointer to a word of storage to be used for the correlation word for the object. If NAME is not provided, PLOT will obtain a word from free storage and the value of the procedure will be a pointer to the word obtained. AFTER is a pointer to the correlation word of the object after which, in the display sequence, the new object should be plotted. If AFTER is not provided, the new object will be added to the end of the display file.

   b. Procedure DISPLAY
      Purpose: To send the display file, or a portion of it, to the terminal.
      Calling Sequence: DISPLAY (HERE*, THERE*)
      Where: HERE is a pointer to the correlation word of the first object to be displayed.
      THERE is a pointer to the correlation word of the last object to be displayed. HERE must precede THERE in the display sequence. If no arguments are provided, the entire display file will be output to the terminal.

   c. Procedure RMV
      Purpose: To remove objects from the display file.
      Calling Sequence: RMV (HERE*, THERE*)
      Where: All objects between HERE and THERE will be removed from the display file. HERE and THERE have the same meaning as for DISPLAY.

   d. Pointer Procedure RPL
      Purpose: To replace an object in the display file with another.
      Calling Sequence: NAME=RPL (NEW, OLD, NAME*)
      Where: NEW is a pointer to the object to replace OLD.
      NAME is the pointer to the correlation word of the new object. If NAME is omitted, the system will supply the correlation word, as is done in PLOT.

VII. INPUT PROCESSING

The sample program can receive input from both the keyboard and graphic input devices, and it is useful to consider the graphics terminal user as having an "extended keyboard" consisting of a typewriter, light pen and/or position input devices, push buttons, etc. In the sample program all input is handled via one input routine, GET.ITEM, which is called with the type of input item to be read.

In the call to GET.ITEM the allowable type of item expected by the program is indicated. In this program the program flow is controlled by the use of "light buttons" and only one type of input is allowable at a given time. In case of an error GET.ITEM could indicate to the user the type of input he was expected to provide and give him an opportunity to correct his error.

GET.ITEM uses a special purpose AED system RWORD processor (5). The allowable input types in the program are:

1. Numeric value.
2. Character string.
3. Graphic input item containing the absolute position of the cursor.
4. Graphic input item containing the information regarding a "pensee" (X,Y cursor coordinates, pointer to the correlation word of the object seen, and the stack of subpicture calls and subpicture definitions, if any). This item will replace an item of type 3 if the cursor is positioned over a pen-sensitive picture element.

GET.ITEM calls upon system routines that examine the contents of the input buffer and decide what types of input items have been received, performing type conversions when necessary and doing some processing such as the cursor correlation function. Different versions of GET.ITEM are required for each type of display console, due to different input message formats, but the user's interface to GET.ITEM is independent of the type of display upon which he is working.

The use of GET.ITEM allows the graphics programmer not to worry about attention or interrupt handling. Input from a display terminal is handled by the M.I.T. timesharing system (CTSS) in much the same way as it handles input from type-writers. When an executing program requests input from the terminal and none has been provided, the timesharing super-visor places the program in "input wait" status and it is removed from the queue of programs waiting to execute. The ARDS transmits information on a character-by-character basis via its telephone line connection to a small communications computer, which assembles a line of input. When the "carriage return" character is received, and the user's program is in input wait status, the timesharing supervisor removes the user's program from input wait status and queues it to run; it can then read the input.

If, on the other hand, the user's program is executing when input is received, the program is not interrupted and the program must specifically request the input in order to determine if it has arrived. The user's

program can read the line of input and act upon it in any way. There may be a considerable time delay between the time the user indicates an action is to be performed and any confirmation is received from his program. All information from the ARDS is transmitted in terms of characters; for example, the cursor position is encoded as a sequence of character codes. The M.I.T. timesharing system therefore simply regards the ARDS as a "high-speed teletype", although other techniques for handling the terminal in timesharing may be preferable for some applications.

If the user of a display console equipped with a light pen and function keys is working continuously, but his program receives only intermittent service in the timesharing system, input from the display console must be buffered in some way so that his program does not lose any of the input intended for it. In the M.I.T. timesharing system, the highly interactive consoles are connected to small computers (PDP-7 or PDP-9) which handle all real-time interrupts. When the small computer has some information for the user's program in the timesharing system, it signals that it has a message which can be read by the timesharing system at its convenience; if the user's program is waiting for input, it will be queued for execution. The small computer can confirm that the user's graphic input has been received, and "package" the information in a convenient form for transmission to the timesharing

system; in the case of a pensee the message would include the pen coordinates, the address in the small computer memory corresponding to the interrupt and the subpicture call stack, which is needed in order to fully interpret a pensee. When the user's program begins to run on the timesharing system, the message received from the display buffer computer can be processed.

VIII. AED LANGUAGE FEATURES

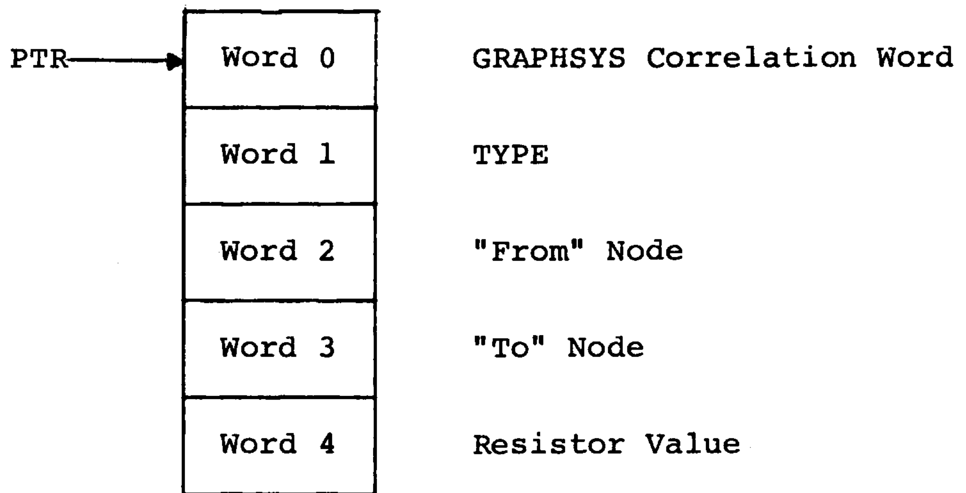
In order to study the sample program, one must be familiar with some of the features of the AED language in which it is written. AED is an extension of ALGOL and includes many features especially suited for building large systems and for manipulating complex data structures. (6,7) A knowledge of ALGOL sufficient to understand the sample program in detail can be obtained from any ALGOL primer, such as the one written by McCracken (8).

The most important AED features used in this program which are not included in ALGOL are the free storage system, the representation of character strings, pointer variables, and components. In our previous discussion we have used the term "bead" to describe a block of storage used for some particular purpose, such as to represent all the information about a resistor. To create a new bead by obtaining it from a list of available storage, the system procedure FREE is called as follows:

PTR = FREE (N) $, (the $, is the AED statement delimiter)

The result of executing this statement will be that the pointer variable PTR will point to a block of contiguous storage N-words long. A pointer in AED on the IBM 360 or 7094 has as its value an absolute core location; the value of PTR is the address of the first word of the block of storage allocated by FREE. The bead can be returned to the list of available storage by calling procedure FRET.

If such blocks are to be useful, the programmer should have a way to refer to individual items within a block; for example, in working with a resistor bead, he would want to refer individually to the name and value of the resistor and also to each of the two connections to the nodes. The ability to name items within a bead is provided by the AED "component" declaration statement and the $=$ assignment operator. Assume that a bead representing a resistor is to have the following format:



To indicate that each bead would have this layout, one would first have to decide to use mnemonics such as TYPE, FROM, INTO and VAL for words 1-4 of the bead. These names would then be used in the declaration statements:

```
INTEGER COMPONENT TYPE $,
REAL    COMPONENT VAL    $,
POINTER COMPONENT FROM, INTO $,
```

Note that unlike arrays, each component of a bead can have a different type.

In order to use a component one must indicate in which bead the component is to be found, since there will be many similar beads all representing resistors. The pointer returned by the call to FREE uniquely identifies the bead in which a component is located; the AED notation to assign a value to VAL in the bead whose pointer is P would be

```
VAL (P) = 7.2 $,
```

(This is read "Val of P equals 7.2".)

Obviously the system must know which word in the bead pointed to by P the user considers to be VAL; this assignment is carried out by the $=$ operator which is evaluated at compile time. To set VAL to be the 4th word in all resistor blocks, one would insert the statement

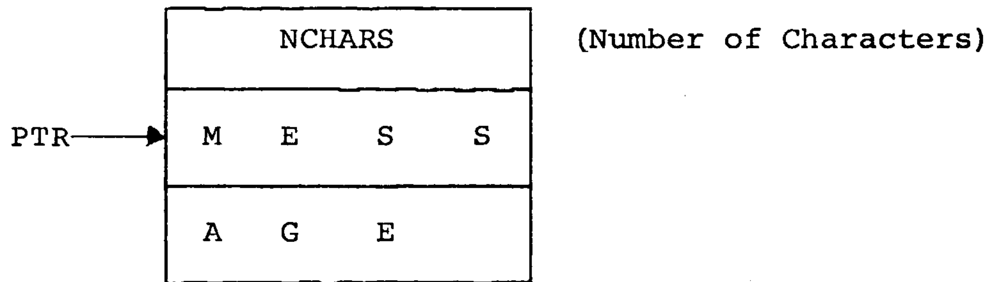
```
VAL $=$ 4  $,
```

in the program following the statement where VAL was declared to be a component. At execution time the expression VAL (P) = 7.2 $, is evaluated as "take the location given by the pointer P, add 4 to it and store 7.2 in that location."

Character strings are manipulated in AED by the use of the .C. operator and pointers. For example, the statement

```
PTR = .C. /MESSAGE/ $,
```

will result in PTR being a pointer to a bead containing the number of characters and the text in the following format:



PTR can therefore be stored in a data structure which has been designed without considering the maximum number of characters in the text string.

A powerful feature of the AED language is the use of phrase substitution, which permits substituting for a variable any construct whose value agrees in type with the variable. For example, suppose a programmer wants to set P to be the square root of A and transfer to statement label SOLVE if the square root is positive. In AED he could write this in one of two forms

```
P = SQRT (A)  $,
IF P GRT  0.  THEN GOTO   SOLVE  $,
```

or by using phrase substitution

```
IF   (P=SQRT (A)) GRT 0.  THEN GOTO   SOLVE   $,
```

The latter case allows the compiler to generate slightly more efficient code. A statement involving phrase substitution can always be simplified by writing out each step in turn, starting with the innermost set of parentheses.

Nested AED procedure calls are used frequently in the sample program; for example, to plot an invisible line of

length $\Delta x = 50$, $\Delta y = -50$ one writes

```
PLOT (INVIS (LINE (50,-50)))  $,
```

which corresponds to

```
PTR = LINE ( 50,-50)  $,
```

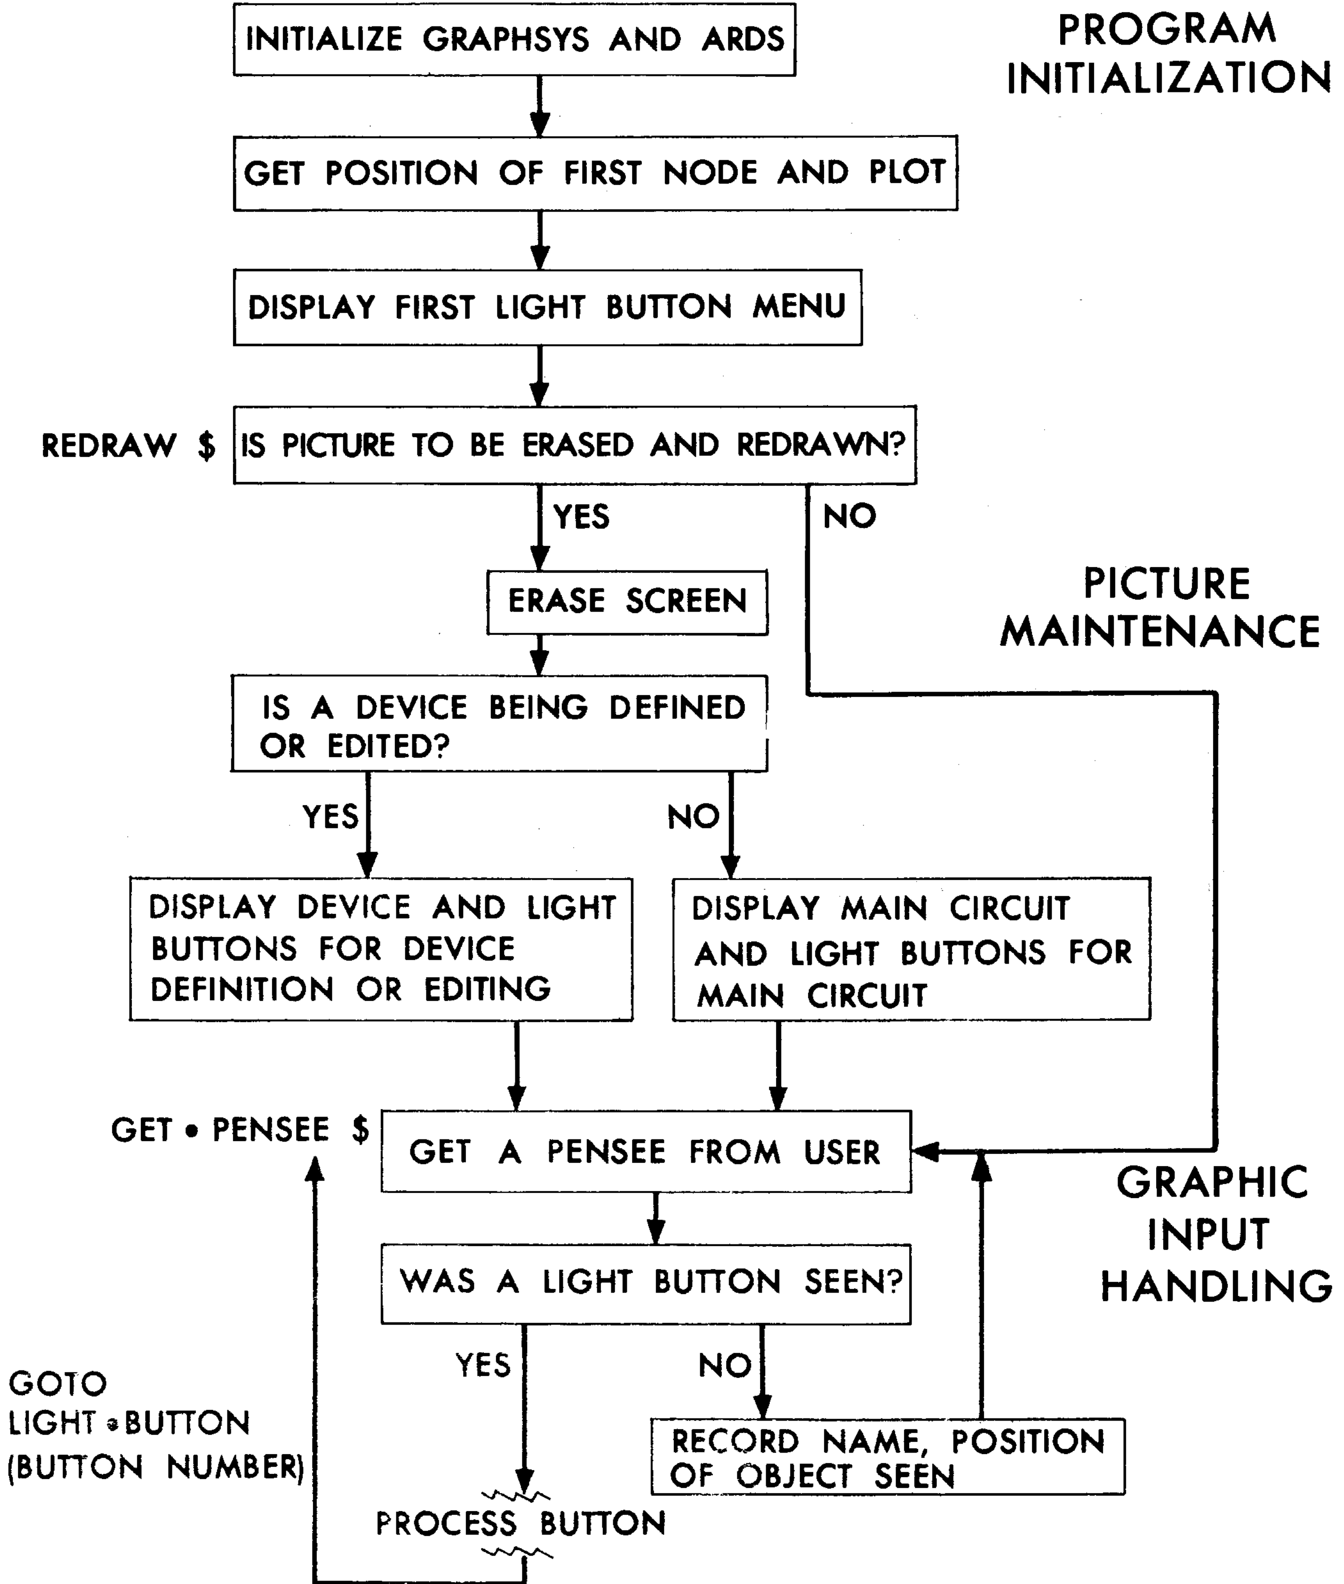
where PTR is a pointer to the object representing the desired line, followed by

```
PTR = INVIS (PTR)  $,
PLOT (PTR)  $,
```

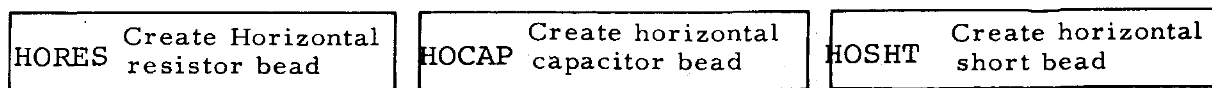
INVIS modifies the line command rather than making a new copy. All of the procedures in GRAPHSYS which manipulate display objects and which are valued procedures have a pointer as their value.

Other features of AED which are likely to be confusing have been commented upon in the program listing. It is hoped that the following set of flow diagrams and the comments in the program will make the program meaningful to anyone seriously interested in the details of its operation.

MAIN PROGRAM LOOP



Process Buttons
HORES, HOCAP, HOSHT



HORIZ $

Find nearest node to last pensee

Find or define node at next horizontal grid position

Connect element to nodes and nodes to element

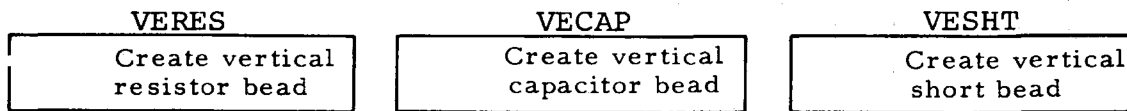
Increase count of leads from both nodes

ALL $

Get name and value for resistor or capacitor

Plot picture of element at proper x, y position

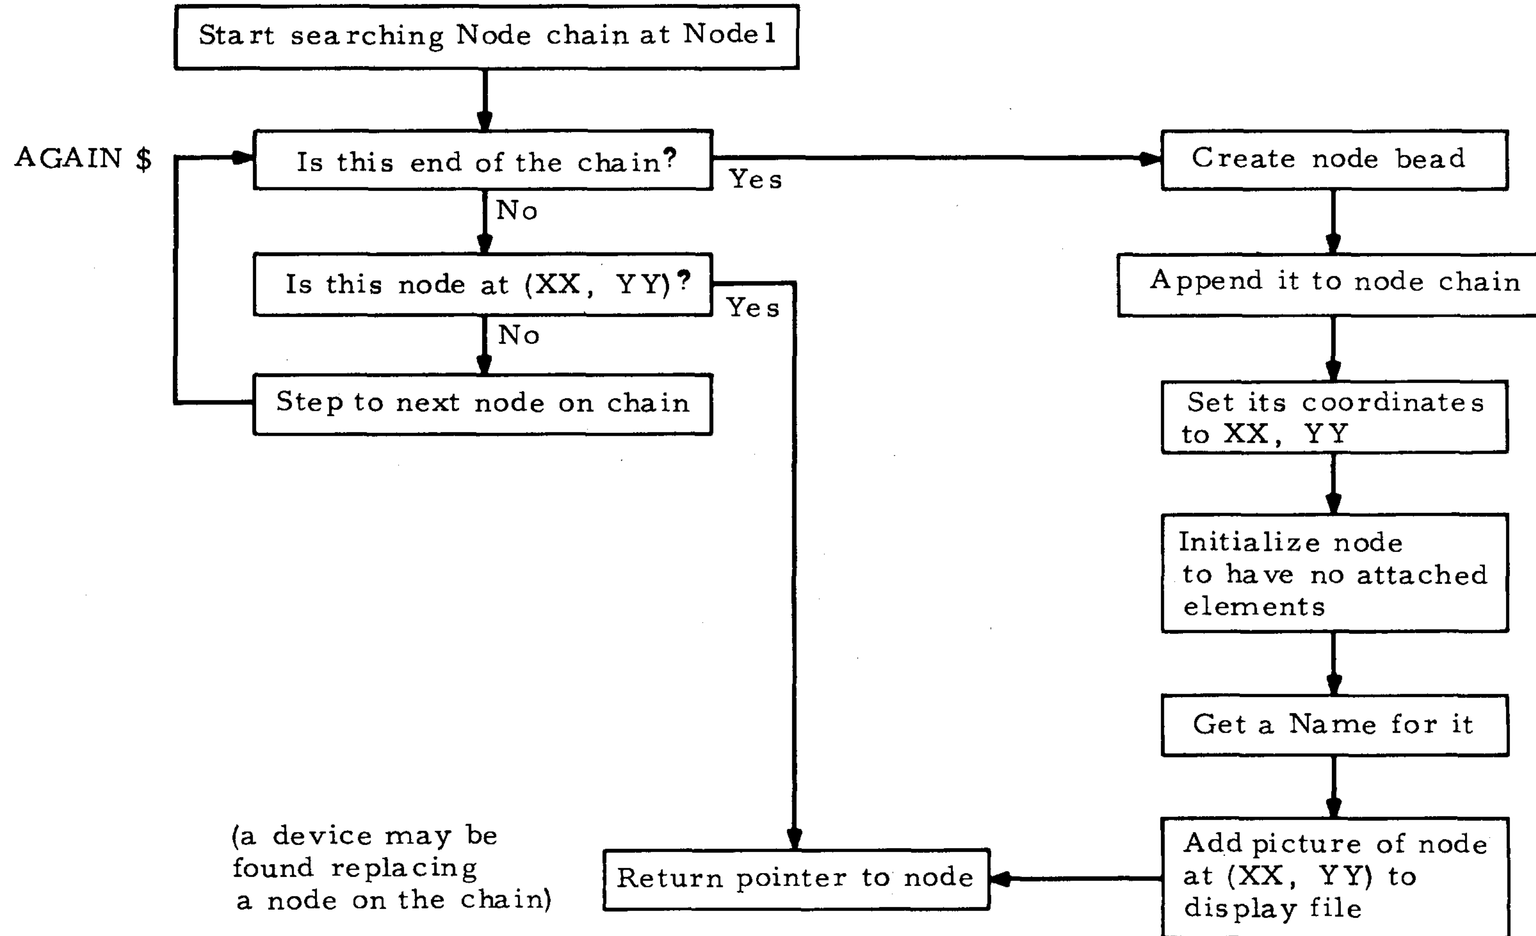
Goto GET.PENSEE



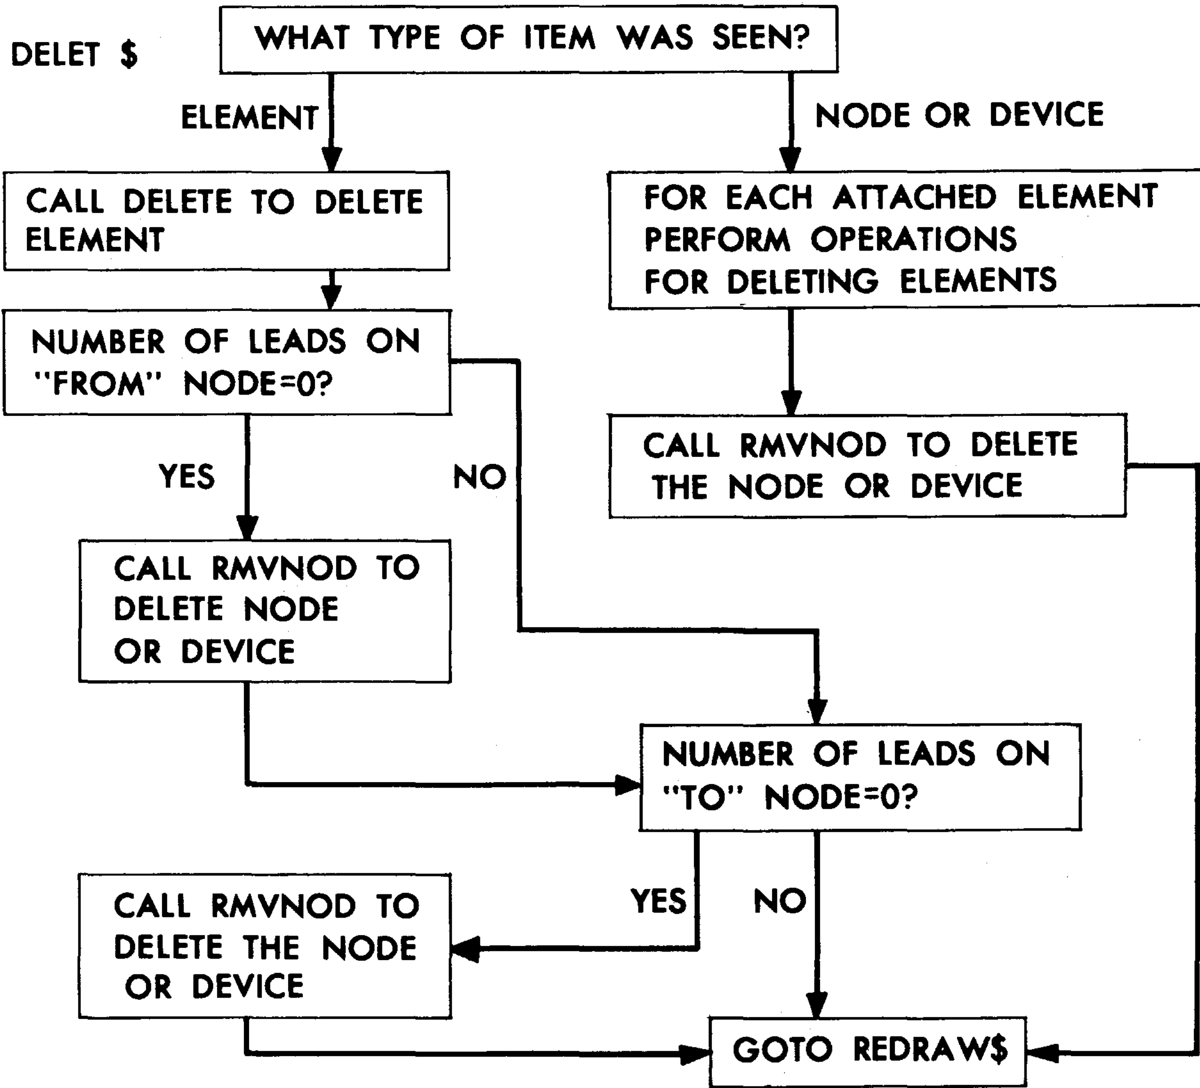
Remainder of flow diagram same as for buttons above, except, replace "horizontal" by "vertical" in 2nd top box.

GETNODE(XX, YY)

Find or create Node bead at (XX, YY)

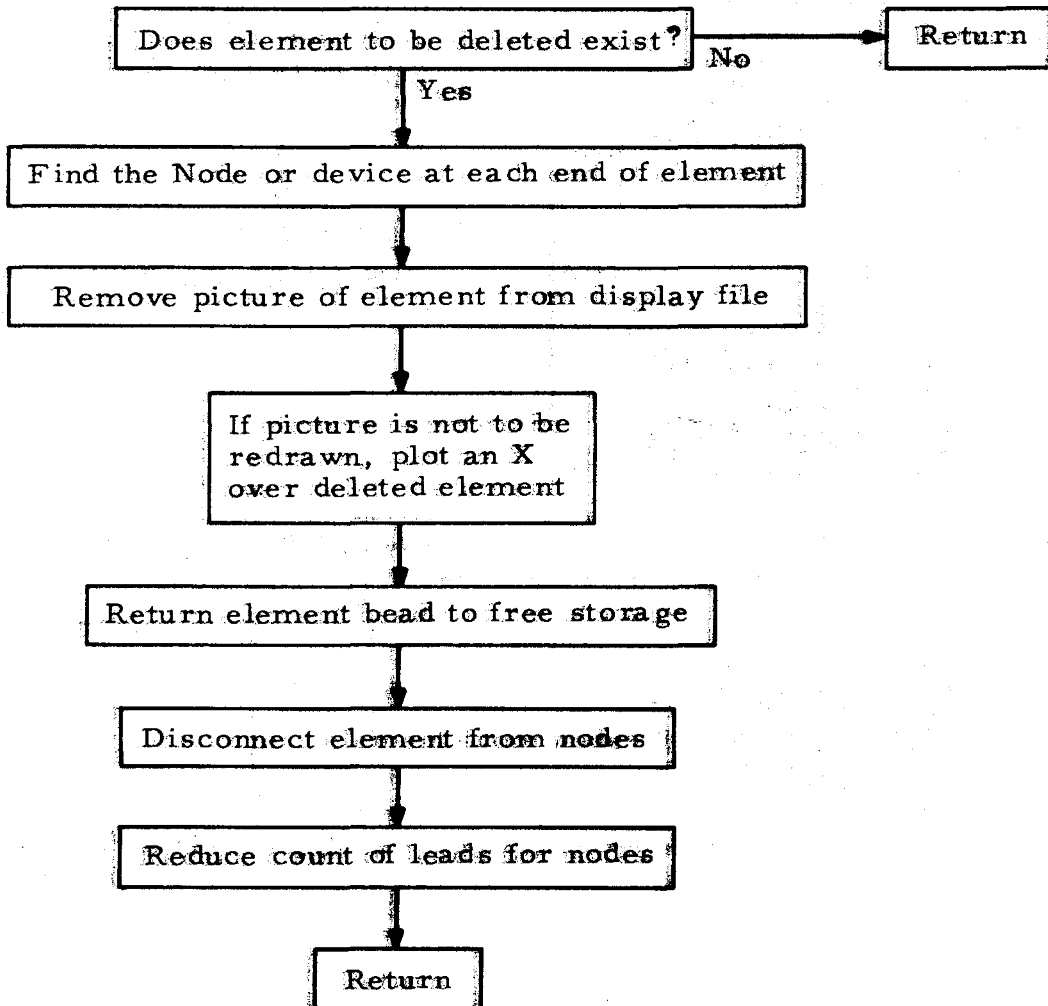


PROCESS DELETE BUTTON



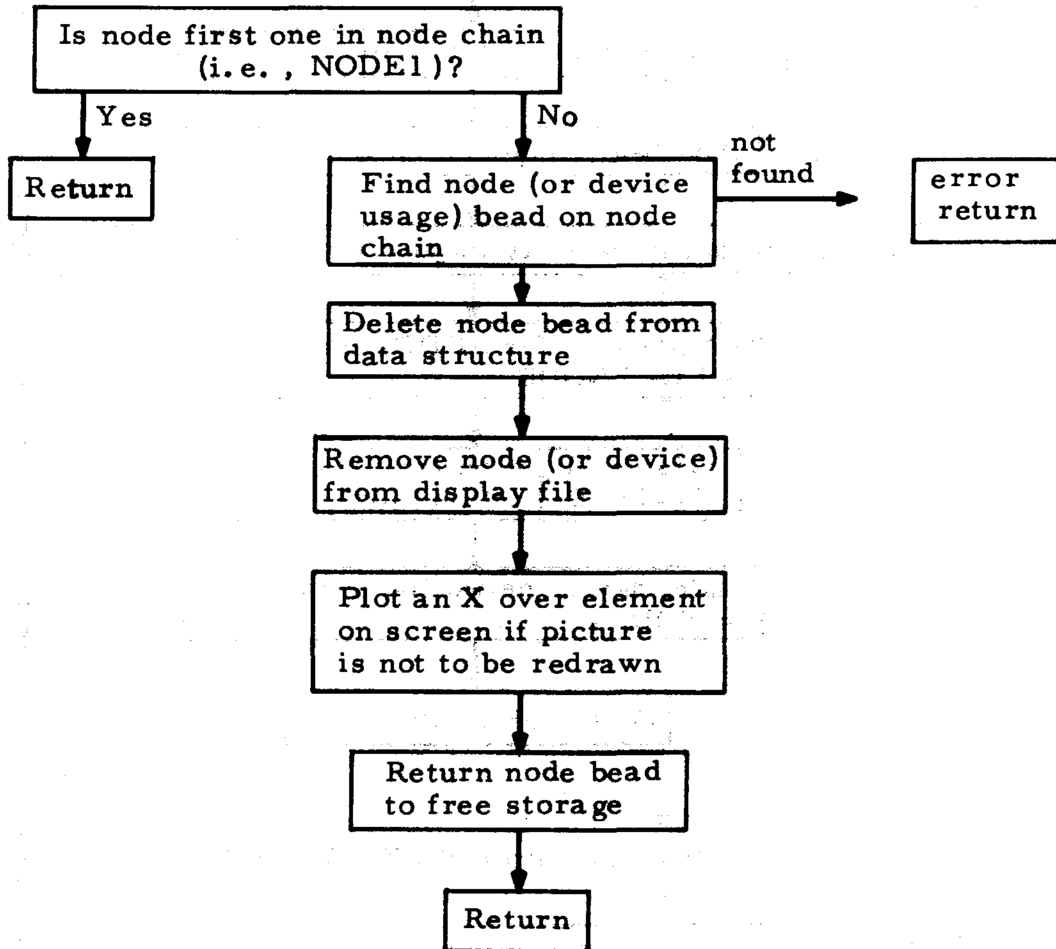
DELETE (ELEMENT, FROMNODE, TONODE)

Delete an element connected between FROMNODE and TONODE

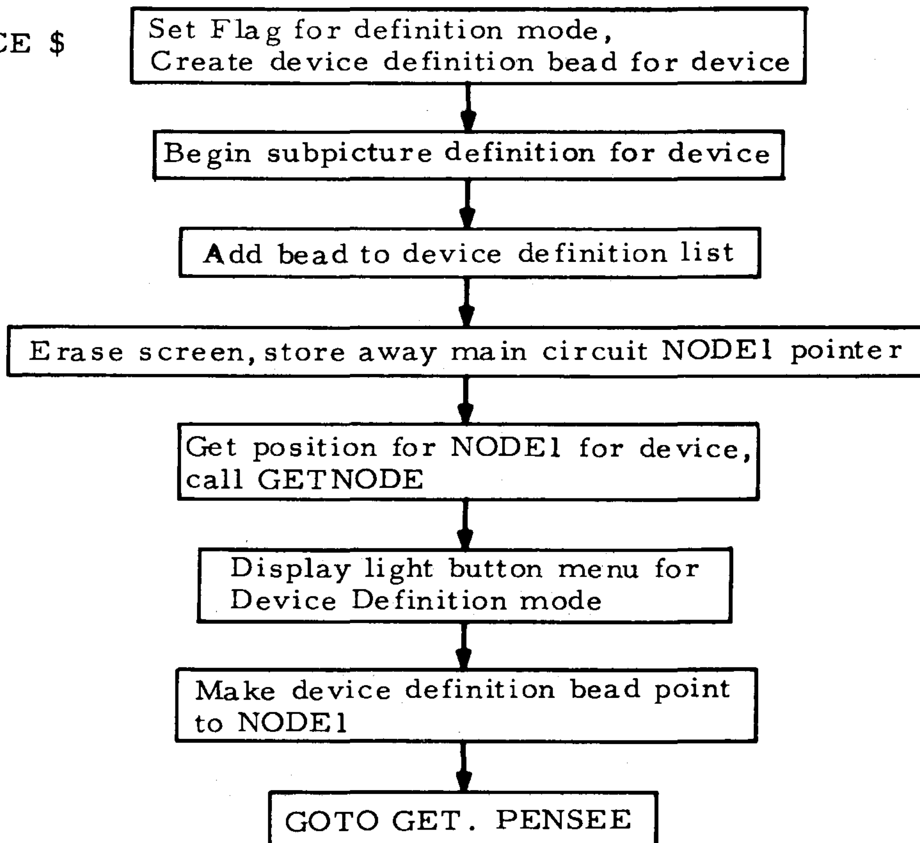


Procedure RMVNODE (NODE)

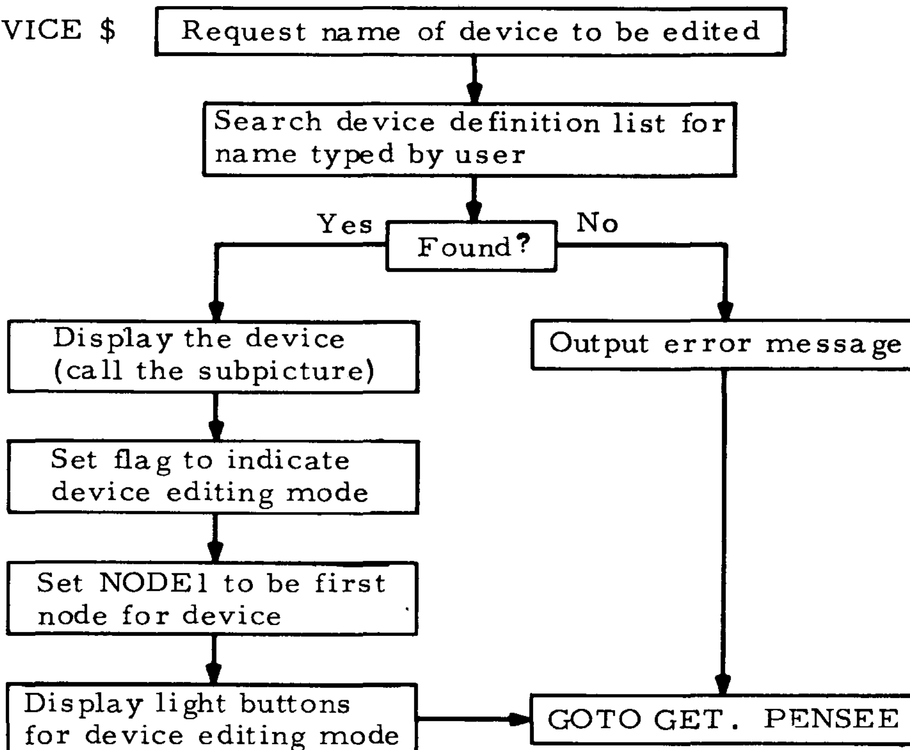
Delete a node from the data structure and display file



Process Button DEF. DEVICE

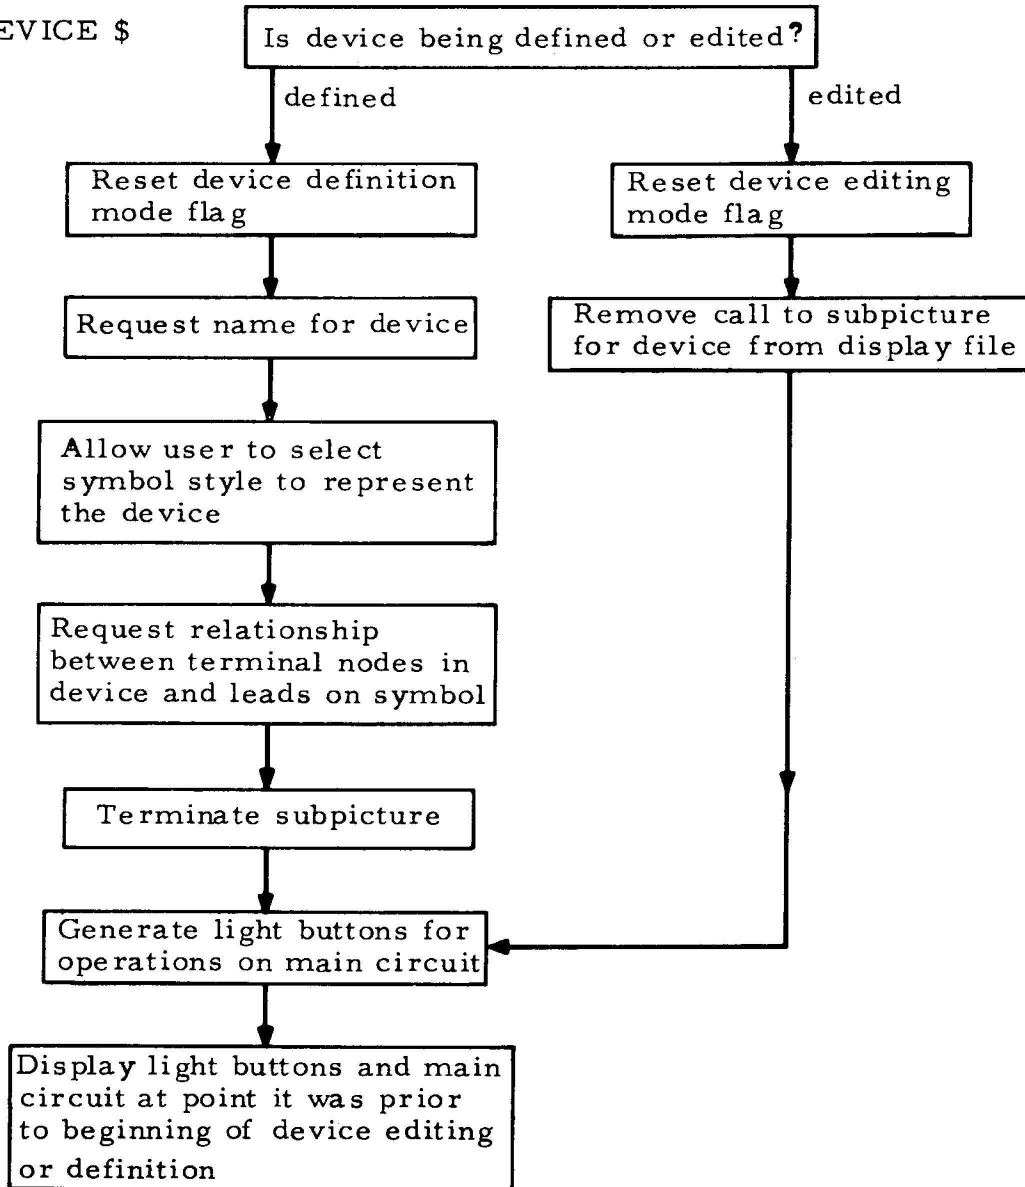


Process Button EDIT. DEVICE



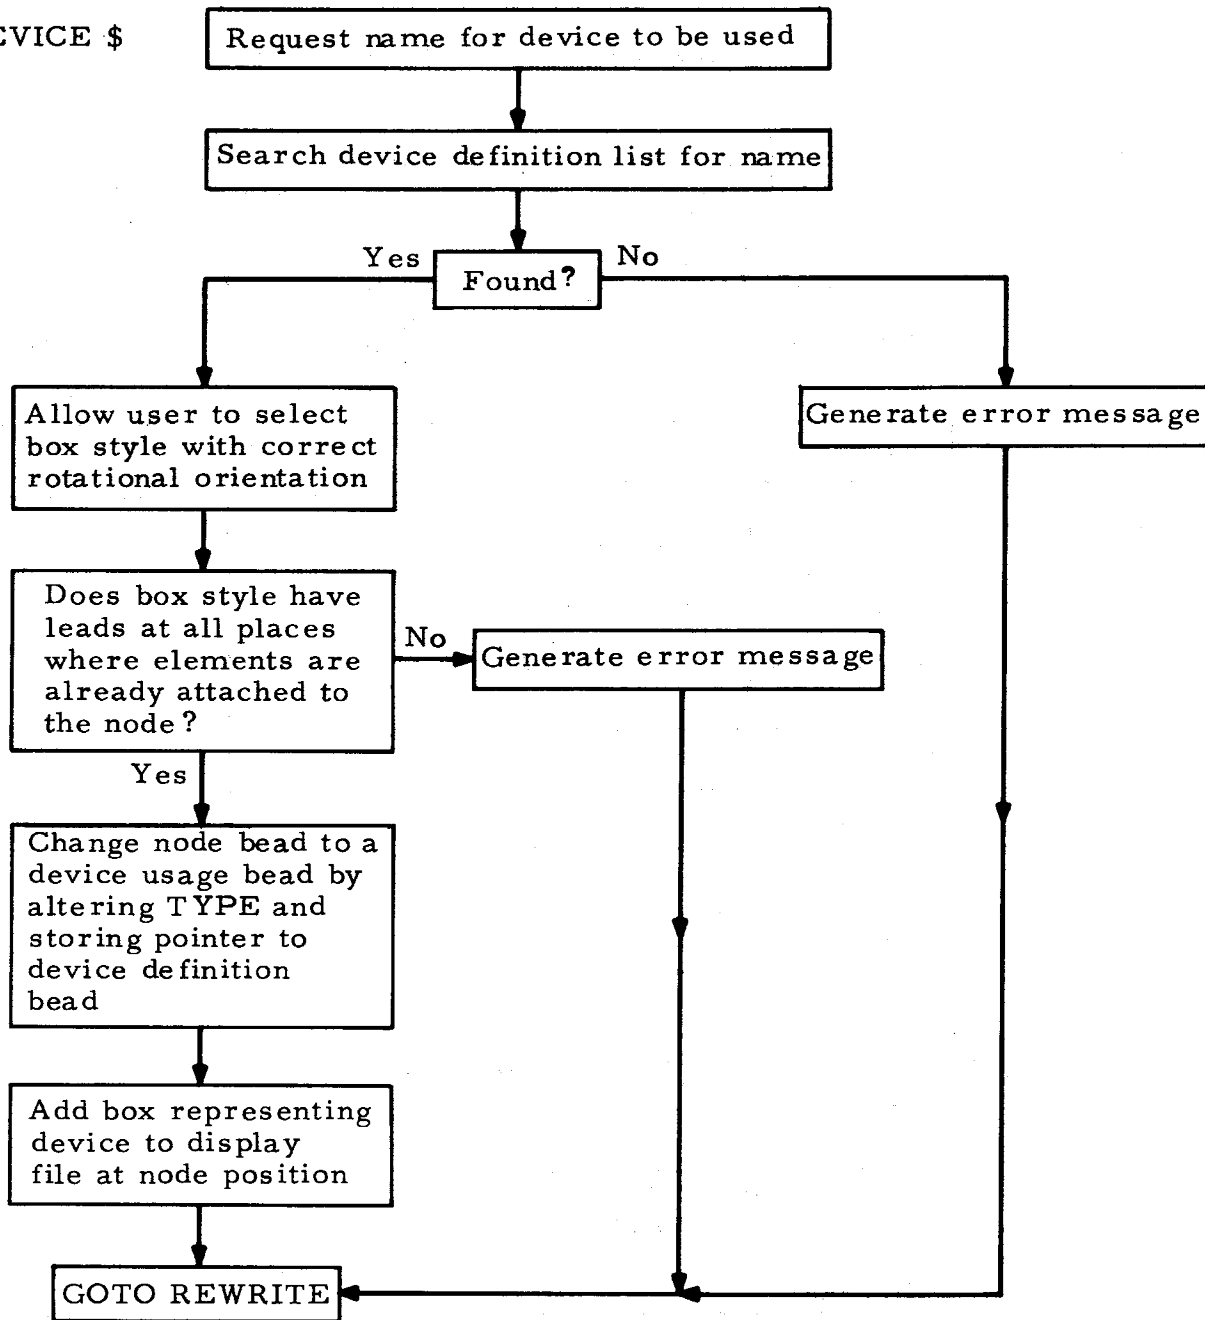
Process Button TERM. DEVICE

TERM. DEVICE $



Process Button USE. DEVICE

USE. DEVICE $



IX. PRINCIPAL LIMITATIONS OF THE SAMPLE PROGRAM

The limitations inherent in the sample program are probably obvious to anyone familiar with circuit design. Several restrictions are basic to the program design:

1. The circuit must be laid out on a fixed rectangular grid, and circuit elements may be attached only between neighboring grid positions. An arbitrary layout of elements is desirable; in the program components may not be arbitrarily located, rotated or scaled on the grid.

2. Circuits larger than those that can be displayed on the screen at one time cannot be constructed; a "windowing" capability is required.

3. The data structure used by the problem cannot use secondary storage, thereby also restricting the size of the circuit that can be designed.

4. The technique for performing correlation assumes that any of the data which might correspond to a pensee is in core.

5. The treatment of devices is very crude in several respects:
   a. Devices should be able to have an arbitrary, user-designed symbol used as their circuit representation.
   b. A device should have an arbitrary number of leads by which it can be connected, not the maximum of four imposed by the grid layout.
   c. The leads of a device should be identified, and the user asked to indicate how each lead should be connected. When the device is being placed

upon a rectangular grid, the present program assumes certain attachments when others are specified. The selection of the proper orientation of an arbitrary symbol for a device, including reflections, translations and rotation, is difficult.

6. The program contains no analysis programs nor does it store more than a trivial amount of numeric data of the type needed by analysis programs.

If all of these restrictions were removed, the program listing would probably triple in size, at least. A more useful system is AEDNET, a large subsystem for analyzing non-linear networks, which is described in references 9 and 10. It was written using AED and GRAPHSYS and has restrictions 1,2,3,5 and 6 removed.

Project MAC — Technical Report Abstract

1. ORIGINATING ACTIVITY
Massachusetts Institute of Technology
Project MAC

2a. REPORT SECURITY CLASSIFICATION
UNCLASSIFIED

3. REPORT TITLE
Case Study in Interactive Graphics Programming: A Circuit Drawing and Editing Program for use with a Storage-Tube Display Terminal

4. DESCRIPTIVE NOTES
Technical Report

5. AUTHOR(S)
John W. Brackett, Michael Hammer, Daniel E. Thornhill

6. REPORT DATE
October 1969

7a. TOTAL NO. OF PAGES
94

7b. NO. OF REFS
10

8a. CONTRACT OR GRANT NO.
Office of Naval Research, Nonr-4102(01)

b. PROJECT NO.
NR-048-189

c. RR 003-09-01

9a. ORIGINATOR'S REPORT NUMBER
MAC TR-63

9b. OTHER REPORT NO.
AD 699-930

10. AVAILABILITY/LIMITATION NOTICES Defense Contractors may obtain from: Defense Documentation Center, Document Service Center, Cameron Station, Alexandria, VA 22314

Others from: Clearinghouse for Federal Scientific and Technical Information (CFSTI)
Sills Building, 5285 Port Royal Road, Springfield, VA 22151

11. SUPPLEMENTARY NOTES
None

12. SPONSORING MILITARY ACTIVITY
Advanced Research Projects Agency
3D-200 Pentagon
Washington, D. C. 20301

13. ABSTRACT

The concepts involved in building and manipulating a data structure through graphical interaction are presented, using the drawing and editing of electrical circuits as a vehicle. The circuit drawing program was designed to operate on an ARDS storage-tube display terminal attached to the M.I.T. Project MAC IBM 7094 Compatible Time-Sharing System. The graphics software system (GRAPHSYS) developed by the M.I.T. Computer-Aided Design Project was used for dealing with all graphical input and output, and the AED Language of the Project was used in programming. AED System packages for building and manipulating complex data structures are described and their use is illustrated in detail. The report includes flow diagrams and complete listings of the sample circuit drawing and editing system.

14. KEY WORDS

Computer Graphics	Graphic Terminals	Display Software System
On-Line Computers	Computer-Aided Design	
Time-Shared Computers	AED Software	

Scanning Agent Identification Target

Scanning of this document was supported in part by the **Corporation for National Research Initiatives,** using funds from the **Advanced Research Projects Agency** of the **United states Government** under Grant: **MDA972-92-J1029.**

The scanning agent for this project was the **Document Services** department of the **M.I.T Libraries.** Technical support for this project was also provided by the **M.I.T. Laboratory for Computer Sciences.**
